## A GENERAL DISCUSSION ON THE PHENOMENA OF POLYMERISATION AND CONDENSATION.

*Thursday, 26th September to Saturday, 28th September, 1935.*

THE SIXTY-THIRD GENERAL DISCUSSION OF THE FARADAY SOCIETY (being the fourth Colloid Meeting organised by the Colloid Committee of the Faraday Society, which comprises representatives of the Royal Society, the Biochemical Society, the Chemical Society, the Faraday Society, the Physical Society, the Physiological Society, and the Society of Chemical Industry), was held in Cambridge from the 26th to 28th September, 1935, inclusive.

The subject under discussion was "The Phenomena of Polymerisation and Condensation," the papers being considered under the two main headings: (1) General and (2) Special.

The meeting was held in the Zoology Department of the University of Cambridge by courtesy of Professor Stanley Gardiner, the President Mr. W. Rintoul occupying the Chair throughout the meeting. By the courtesy of the Master and Fellows, members and guests were accommodated in Pembroke College, a considerable overflow staying, however, at the Bull Hotel. Those staying at the Bull Hotel were able to join the party in College for meals. Morning coffee and afternoon tea were taken in the Department of Zoology.

The Guest Night Dinner was held on Friday, 27th September, in Hall. There were no formal speeches, but the toast of the overseas guests was proposed by Professor Donnan and replies by Professor Staudinger, Professor Kurt Meyer, Professor Mark, Professor Katz and Dr. Carothers were called for. The toast of the Master and Fellows of Pembroke College was proposed by the President and Mr. S. C. Roberts replied. Toasts were also accorded to Professor Rideal and Mr. Wansbrough-Jones.

At the Inaugural Meeting the Vice-Chancellor of the University, Mr. J. F. Cameron (the Master of Caius and Gonville) welcomed the Society to Cambridge and took the opportunity of paying a tribute to the memory of Sir William Hardy on whose initiative the Colloid Committee of this Society was formed. The President then introduced the overseas guests, members and visitors and called upon them each to rise in his place, whereupon they were welcomed with acclamation. Those so welcomed were: Dr. L. Altwegg (*Paris*), Dr. E. Bergmann (*Rehoboth*), Dr. J. H. de Boer (*Eindhoven*), Dr. T. F. Bradley (*Linden, N.Y.*), Dr. W. H. Carothers (*Wilmington Del.*), Dr. H. Dostal (*Wien*), Dr. F. Eirich (*Wien*), Dr. R. Houwink (*Eindhoven*), Professor and Mrs. J. R. Katz (*Amsterdam*), Mr. and Mrs. R. H. Kienle (*Bound Brook, N.Y.*), Professor P. N. Kogerman (*Tartu*), Frln. Dr. D. Kruger (*Berlin*), Professor H. Mark (*Wien*), Professor M. Mathieu (*Paris*), Professor Kurt H. Meyer (*Genthod-Genève*), Dr. R. Meyer (*Paris*), Dr. J. van der Minne (*Amsterdam*), Dr. Orthner (*Frankfurt*), Dr. J. C. Patrick (*Yardville, N.Y.*), Professor H. Pringsheim (*Prag*), Dr. E. Proskauer (*Leipzig*), Dr. G. Salomon (*Zurich*), Dr. Sauter (*Freiburg i. Br.*) Professor and Mrs. Signer (*Bern*), Professor H. Staudinger (*Freiburg i. Br.*), Professor

T. Takei (*Tokyo*), Dr. P. von Tavel (*Bern*), Dr. J. C. Vlughter (*Amsterdam*), Professor H. I. Waterman (*Delft*), Dr. A. Weidinger (*Amsterdam*), Professor F. Weigert (*Leipzig*), Dr. H. B. Weiser (*Houston, Tex.*).

**Professor E. K. Rideal** then said: In the first place I would like to thank, both on your behalf and personally, our Vice-Chancellor for devoting the time to open our discussion. To those of you who are not acquainted with our University I can give the assurance that the Vice-Chancellor is our busiest representative.

I wish also to extend a cordial invitation to those present to inspect the laboratory of Colloid Science. It is a relatively small laboratory, but we have attempted to make it a convenient and pleasant place to work in.

Finally I would like to draw your attention to the fact that the scientific works of the founder of the Colloid Committee of the Faraday Society, Sir William Bate Hardy, F.R.S., will be published shortly by the Cambridge University Press, who have provided us with a number of sample partly-printed copies for inspection. As some of you may remember, the cost of publication has been estimated at about one thousand pounds; towards which the Cambridge University Press have most generously provided three hundred pounds. I have to thank Hardy's College, Gonville and Caius, the Royal, Physiological, Chemical, Biochemical and our own, the Faraday, societies, the dominions of South Africa, Australia, and New Zealand, and particularly the Premier of the latter, for interesting themselves in this matter. I would also like to express my indebtedness to Lady Hardy and Dr. E. C. and Mrs. Smith, for their valuable assistance in the collecting of the papers.

I trust that we as a Society shall welcome this publication, which as you well know contains a numbers of papers classic in our science.

At the conclusion of the meeting a vote of thanks was accorded at the instance of the President to the overseas guests, whose presence had particularly contributed to the success of the meeting. Professor Kurt Meyer replied on behalf of the overseas guests, and said that they would all be very glad to come again to meetings of the Society. On the motion of the President a vote of thanks was accorded to Professor Gardiner and the staff of the Department. The Secretary proposed a vote of thanks to the Master and Fellows of Pembroke College and mentioned the great difficulties under which the College was labouring owing to the recent death of three senior Fellows and, only ten days ago, of the Bursar, Mr. H. G. Comber. They would all, he knew, endorse his action in writing to the Master and expressing the Society's sympathy with the College. The smooth way in which the arrangements for their comfort had been carried out reflected great credit on the servants of the College and those Fellows who had carried on its work. This was received with sympathy. The President also proposed votes of thanks to the contributors of papers, to Dr. Rabinowitch for his translations, and to the Colloid Committee and the sub-committee, particularly Professor Rideal, for organising and arranging the meeting. The proceedings closed with a vote of thanks to the President and the Secretary.

The report of the meeting, including all the papers contributed and the general discussion thereon, appears in the following pages :

is identical with the curve (curve *b*) for the van der Waals attractive energy, for distances greater than 4 Å., and while further it is assumed, on the basis of data for other molecules<sup>48</sup> that, when the equilibrium distance, i.e., the position of the potential minimum lies at 3.7 Å, the energy content is again zero at 3.4 Å. In the calculation (curve

*b*) the van der Waals reciprocal energy is set equal to  $\frac{C}{r^6}$  whereby *C* is calculated according to the Slater-Kirkwood approximation formula when an average value  $\alpha_0 = 1.7 \times 10^{-24}$  is taken for the polarisability. Thus

$$C = 805 \times 10^{-48} \text{ kg. cal. } \times \text{ cm.}^6$$

If we let the two benzene rings approach each other along a line perpendicular to both rings then the six CH groups which are closest to each other (the pairs 1-1', 2-2', etc. in Fig. 4 will be in unfavourable positions with respect to the anisotropy of the polarisability. In order to take this into account, we use the formula mentioned in § 3:

$$C = \alpha_0^2 (\alpha_a^{3/2} - \alpha_b^{3/2} + 4\alpha_c^{3/2}) \frac{h\nu_0}{8}$$

for which we calculate  $h\nu_0$  by substituting for *C* the value of *C* according to the approximation formula of London,  $C = \frac{3}{2} \alpha_0^2 h\nu_0$  and for *S* the experimental value ( $S = 10.67$  kg. cal./mol) in the expression

$$S = \frac{0.0277}{2} C \quad (\text{cf. § 5}).$$

We thus obtain  $h\nu_0 = 353$  kg. cal. In Fig. 15, curve *a* represents the respective reciprocal energy of the six pairs of CH groups which lie opposite each other, calculated with the aid of a value of *C* which takes into account the anisotropy ( $C = 592 \times 10^{-48}$  kg. cal.  $\times$  cm.<sup>6</sup>), while curve *b* gives the total reciprocal energy of both benzene molecules, whereby, as in § 3, no account is taken of the anisotropy for pairs of CH groups, which do not

FIG. 15—Potential energy of two benzene molecules, lying in parallel planes, as a function of the distance between the molecules (curve *b*). Curve *a* represents the reciprocal energy of the six pairs of CH groups which lie opposite each other.

lie opposite each other ( $C' = 770 \times 10^{-48}$  kg. cal.  $\times$  cm.<sup>6</sup>). Although,

<sup>48</sup> Cf. table in H. A. Stuart's *Molecular Structure*, Berlin, 1934, pp. 36 and 262.

therefore, at distances slightly less than 3.7 Å. the pairs of CH groups directly opposite each other are situated upon the repulsion branch of the potential curve, the molecules taken as a whole nevertheless attract each other with increasing force until the potential minimum for the whole molecules is reached at 3.5 Å. It is evident, further, that at a mutual separation of 3.2 Å. the energy content is still only slightly negative, while at 3.1 Å. the repulsion is already so great that 3 to 4 kg. cal. would be necessary to cause the molecules to approach to this distance.

Therefore, if two or more benzene rings in a molecule must be brought so close to each other, this occurs at the cost of the energy content of the molecule. It may be that the easy dissociability of hexaphenyl-ethane into two triphenyl-methyl radicals is partially due to this effect. In this case the energy of dissociation is about 12 kg. cal., while on the contrary 71 kg. cal. are necessary to separate two normally bound aliphatic carbon atoms.<sup>47</sup> We must keep this repulsion strictly in mind in the discussion of the orientation in polystyrene.<sup>48</sup>

### 15. Positions of the Benzene Rings in Polystyrene, Assuming a Structure of the Aliphatic Carbon Chain like that in Solid Paraffins.

If we assume that the aliphatic carbon chain in polystyrene has the same structure as the aliphatic chains in the solid paraffins, and if we imagine the phenyl groups substituted on the carbon atoms 0, 2, 4, etc., then we may distinguish several cases A, B, and C.

FIG. 16.—Part of a polystyrene molecule; the  $C_6H_5$  group on the second and the H atom on the fourth carbon atom of the chain stick out from the figure; the H atom on the second and the  $C_6H_5$  group on the fourth carbon atom lie behind the plane of the drawing.

A. The phenyl groups on the second and fourth carbon atoms are situated on different sides of the carbon chain. This is indicated schematically in Fig. 16 in which the  $C_6H_5$  group on the second, and the H atom on the fourth carbon atom must be imagined to stick out from the figure and the H on the second and the  $C_6H_5$  on the fourth carbon atom must be imagined to lie behind the plane of the drawing. We consider the three following

positions under this case :

- (a) That in which both benzene rings lie perpendicular to the direction of the carbon chain (Fig. 17).
- (b) That in which both benzene rings lie parallel to the direction of the carbon chain (Fig. 18).
- (c) That in which one of the benzene rings is perpendicular and one parallel to the carbon chain (Fig. 19).

<sup>47</sup> In the case of still larger aliphatic groups, naphthyl, etc., the dissociation is still easier.

<sup>48</sup> Additional phenomena, connected with the repulsion between two phenyl groups which are very close to each other in the molecule, are the stretched-out form of diphenyl, and the relatively large valence angle ( $142^\circ \pm 8^\circ$ ) of diphenyl ether.

If we keep in mind that, in all positions (especially in position *A c*, Fig. 19), the CH groups of the benzene rings which have approached closest to each other, do not attract each other with the maximum force, but even repel each other appreciably, we come to the conclusion that the benzene rings attract each other in all three positions and that binding energies are :

Position *A a* about 2.4 kg. cal.

" *A b* " 2.3 "

" *A c* " 1.8 "

FIG. 17.—Part of a polystyrene molecule; positions as in Fig. 16; both benzene rings perpendicular to the direction of the carbon chain.

FIG. 18.—Part of a polystyrene molecule; positions as in Fig. 16; both benzene rings parallel to the direction of the carbon chain.

If, further, we remember that in position *A b* the distance between the H atom, which is also attached to carbon atom 4, and the closest CH group of the benzene ring attached to carbon atom 2 is only about 1.8 Å. (calculated to the nucleus of the C atom of the CH group. If the H atom is calculated separately the repulsion becomes still much greater), we see that the combining energy in position *A c* and especially in position *A b* will thereby be much smaller than the above-mentioned quantities indicate (the energy content of the system of two H atoms and two benzene radicals will probably even be positive in these positions because of the strong repulsion between the H atoms and the closest CH groups of the benzene nuclei).<sup>49</sup>

The differences in energy among the three above-mentioned positions therefore become greater than the average kinetic energy at room temperature, so that we arrive at the result that case *A a* is not only by far the preferred one, but also that the benzene radicals, in the cases of linkages which fall under case *A*, will execute oscillations about position *A a*.

FIG. 19.—Part of a polystyrene molecule; positions as in Fig. 16; one of the benzene rings parallel and the other perpendicular to the direction of the carbon chain.

<sup>49</sup> Up to now we have worked only with CH, CH<sub>2</sub>, etc., groups and not with individual H atoms. We might continue this practice, and we must then say that the distance between the closest CH groups of the benzene radical attached to carbon atom 2, for example (in position *A b* or *A c*) is only about 2.6 Å. away from CH group 4, so that these two groups will exhibit a strong repulsion.

**B.** The phenyl groups attached to the second and fourth carbon atoms are situated on the same side of the carbon chain. Since the distance between carbon atoms 2 and 4 is only 2.54 Å., all orientation leads to repulsion, but that in which the benzene rings both lie perpendicular to the direction of the carbon chain, to the smallest extent. One might imagine that the angle at carbon atom 3 would be forced to greater values than  $110^\circ$  by this repulsion. In the completely stretched state, however, the second and fourth carbon atoms are still 3.1 Å. away from each other, so that with parallel orientation the phenyl groups still repel each other slightly. In this latter case the energy content of this grouping would be strongly positive because of the energy necessary for the widening of the angle at carbon atom 3 (this energy would be of the order <sup>50</sup> of magnitude of 15 kg. cal., while the repulsion would add 3 to 4 kg. cal. more).

**C.** The phenyl groups attached to the second and sixth carbon atoms are situated on the same side of the carbon chain. The position in which the benzene rings lie parallel to the carbon chain leads here also to a repulsion, since the distance between the closest CH groups is only 2.58 Å. If both benzene rings are oriented perpendicular to the carbon chain, they attract each other (binding energy about 1.1 kg. cal.), while the most favourable position is that in which one benzene ring is perpendicular and the other parallel to the carbon chain (binding energy about 2.5 kg. cal.). This position is, however, unfavourable as regards the phenyl group attached to the intermediate carbon atom 4 (see under A).

Summarising, we come to the conclusion that when the aliphatic carbon chain is similar to that found in the solid paraffins, the most favourable position of the phenyl groups is that in which they lie alternately to the right and to the left of the chain and perpendicular to the direction of the chain. This is, however, only possible when the other, equally possible stereoisomers cannot be formed during polymerisation. If these latter are formed, and if the chain form is also retained, then the benzene rings certainly lie perpendicular to the direction of the chain, and a weaker spot occurs at that point in the chain.

## 16. Positions of the Benzene Rings in Polystyrene, Assuming Another Structure of the Aliphatic Carbon Chain.

Another possibility is, however, that when the two phenyl groups on carbon atoms 2 and 4 lie on the same side of the chain, the chain will take another form. If one rotates the groups attached to carbon atom 3 about the line joining 2 to 3 by  $180^\circ$ , for example, the configuration of Fig. 20 results. In this case the groups attached to carbon atom 4' will be repelled by the two H atoms on carbon atom 1, but in any case the benzene ring will again take up a position perpendicular to the direction of the chain.

If only these of all possible stereoisomers should occur one might imagine a chain as in Fig. 21. The benzene rings would certainly all be perpendicular to the direction of the chain (the closest CH groups are then about 3.5 Å. apart) so that a strong attraction prevails between the phenyl groups; the intermediate  $\text{CH}_2$  groups, however, exercise a strong repulsion).

<sup>50</sup> Cf. H. A. Stuart, *Molekülstruktur*, Berlin, 1934, pp. 85, 86.

Another possibility may also be reviewed, *viz.*, that whereby the carbon chain is wound in a spiral, so that the seventh carbon atom comes above the first, etc. Because of the van der Waals reaction between the members of the chain themselves, they will have a tendency to seek a mutual separation of about 4 to 4.5 Å. The benzene rings must then be perpendicular to the axis of the spiral.

FIG. 20.—Part of a polystyrene molecule; when the two phenyl groups on carbon atoms 2 and 4 lie on the same side of the chain another form of the chain is possible. In reality a position between the two here denoted is very probable.

FIG. 21.—A repetition of the positions given in Fig. 20.

## 17. Conclusion.

We may expect that various configurations of polystyrene occur due to the various possible stereoisomers in different parts of the carbon chain. Common to all these configurations, however, will be a preference of the benzene ring to take up a position perpendicular to the carbon chain, or at least to execute oscillations about equilibrium positions, in which the benzene ring is perpendicular to that direction. If we remember that the polarisability of benzene in the direction perpendicular to the plane of the ring is only about half that in the plane of the ring, we see that an anisotropy will be present in the polystyrene chain, which will completely dominate that of the carbon chain itself. The carbon chain itself would cause an anisotropy such that the polarisability in the direction of the chain would be greater than in the perpendicular direction. Because of the benzene rings which lie perpendicular to the chain, however, the former anisotropy of the chain itself will be more than compensated for and we obtain the smallest polarisability in the direction of the chain, and therefore also the smallest index of refraction. In our opinion herein lies the explanation of the strongly negative double refraction caused by flow of polystyrene,<sup>51</sup> which must be ascribed to the individual polystyrene molecules.<sup>52</sup>

### Summary.

#### PART I.

The question of the mutual orientation of molecules under the influence of van der Waals' forces is discussed. In general there are two opposing factors, namely: the tendency of the atoms to gather as many neighbours as possible, and the anisotropy of the polarisability. The first of these tendencies practically always dominates over the second. This fact is illustrated with reference to two benzene molecules. In the calculation of the reciprocal energy in the equilibrium state, good results are by chance obtained when use is made of the approximation formula of London or of Kirkwood and Slater, and when the influence of the repulsive forces is neglected. The sublimation energy of benzene, for example, may be satisfactorily calculated in this way.

#### PART II.

The theoretically calculated value of the tensile strength of common salt is very much greater than the value found experimentally. In the theoretical calculation the influence of the van der Waals forces has been thus far neglected. When this is not done, the theoretical value obtained is still much greater, about 400 kg./mm.<sup>2</sup>. If a secondary structure is assumed, such as has been proposed by Zwicky, and if it is likewise assumed that there are no electrostatic forces of any description between the "blocks," the value obtained for the theoretical tensile strength is still much too great. In this case the value obtained is  $> 20$  kg./mm.<sup>2</sup>, while the experimental value is 0.6 kg./mm.<sup>2</sup>. This low experimental value must be ascribed to a notch effect arising from defects in the lattice, and not to a regular secondary structure.

In the case of artificial resins of the phenol-formaldehyde type and the *m*-cresol-formaldehyde type similar relations between calculated and observed values are encountered. If such an artificial resin is completely polymerised throughout its whole mass and all the C—C linkages possible are actually formed, the theoretical tensile strength may be calculated to be about 4000 kg./mm.<sup>2</sup>. If (irregular) "blocks" are assumed in this case also, and if these blocks are assumed to cohere only by means of van der Waals forces, then the theoretical value of the tensile strength is about  $> 35$  kg./mm.<sup>2</sup>. The experimental value is, in this case as with sodium chloride, very much smaller, *viz.*, about 7.8 kg./mm.<sup>2</sup> for the phenol-formaldehyde resin, so that here also an influence of a notch effect is probable. On the other hand, in the case of well-oriented cellulose derivatives, the correct order of magnitude for the tensile strength may be obtained by theoretical calculations.

Young's modulus of elasticity is also dependent on the van der Waals bonds present in the artificial resin.

#### PART III.

The potential curve for the bond between two benzene molecules is examined on the basis of the effects due to the individual CH groups. When the minimum lies at 3.5 Å., the energy content at a separation of 3.2 Å. is only slightly negative, while at 3.1 Å. the repulsion is already so great that 3 to 4 kg. cal. would be necessary to cause the molecules to approach to within this distance.

The relative positions of the benzene rings in polystyrene are investigated, and the conclusion may be drawn that there will be a preference on the part of the benzene ring to lie perpendicular to the direction of the aliphatic carbon chain. This makes understandable the strongly negative double refraction caused by flow.

Many thanks are due to Mr. G. Heller for his valuable suggestions concerning Part I. Part II. owes its existence to several discussions with Dr. R. Houwink, and I am greatly indebted to him for his kindness in putting his experimental figures at my disposal.

(*Natuurkundig Laboratorium der N. V. Philips,  
Gloeilampenfabrieken,  
Eindhoven-Holland.*)

## GENERAL DISCUSSION

Professor J. E. Lennard-Jones (*Cambridge*) said: While I agree that Van der Waals' fields play an important rôle in the phenomena discussed by Dr. de Boer and that it is very desirable to estimate their magnitude, I should like to ask the author whether he thinks the theory sufficiently developed at present to make reliable quantitative calculations. I think the formula given by London was intended only for spherically symmetrical systems and even for them it is only approximate. While it gives the right order of magnitude for the inert gases, it is not yet certain that there is not an error by a factor of two. But the error may be greater in the case of aromatic molecules owing to their lack of symmetry and to their special electronic structure in that they contain "non-localised" electrons. Is it not likely that these will require special treatment?

Professor H. Staudinger (*Freiburg i. Br.*) said: The question whether in the polystyrene molecule, the single styrene molecules are linked according to formula 1 or formula 2 is answered in favour of formula 1 by the following experiments: "

Polystyrene, as is well known, depolymerises very easily, reforming chiefly the monomer, but also some dimer, trimer and higher polymers. The yield of the latter products can be increased by performing the depolymerisation *in vacuo*. The formula of the dimer is

and that of the trimer

It follows that formula 1 and not formula 2 must be attributed to polystyrene. Decomposition products which should occur in the decomposition of a product of the formula 2 could not be observed.

However, as was originally supposed, the constitution of the polystyrenes is more complicated. According to viscosity measurements, products prepared with the aid of catalysts have the constitution of formula 1, for in this case determinations of the molecular weights cryoscopically and by viscosity measurements agree well. The end groups of these molecules remain, however, unknown. The meso- and eucolloidal polystyrenes

<sup>54</sup> Compare H. Staudinger and A. Steinhöfer, *Annalen*, 1935, 517, 35.

obtained by heat polymerisation have a more complicated structure than the hemicolloidal; the molecular weight determined by the viscosity method is smaller than that given by Svedberg's method,<sup>54</sup> and by the osmotic method.<sup>55</sup> In this case unknown branching must have occurred in the formation of the high polymer. By increased temperature of polymerisation these side reactions take place to a greater extent. For this reason it will be difficult to make final calculations on the relations between the size of the molecules and the tensile strength, unless the structure of the molecules is previously elucidated.

Professor K. H. Meyer (*Genève*) said: De Boer has calculated the modulus of elasticity of an artificial phenol-formaldehyde resin with only primary valencies. The value of 11,000 kg./mm.<sup>2</sup> found is far beyond the observed value.

Lotmar and I recently calculated the modulus of a cellulose-chain according to our spacial model, taking into account both the valency-oscillations and the deformation-oscillations (*Knickschwingung*). The calculated value was  $10,000 \pm 2000$  kg./mm.<sup>2</sup> We measured the modulus of well-orientated natural cellulose fibres by an acoustic method, and found that all the fibres tend to a value of about 11,000 kg./mm.<sup>2</sup> This experiment is certainly the most direct proof in favour of the primary valency chain formula of cellulose.

Dr. J. H. De Boer (*Eindhoven*), said, in reply to Professor J. E. Lennard-Jones: It is perhaps possible that some other attractive forces are present in the reciprocal action of two benzene molecules; indeed benzene molecules are not directly comparable with inert gas atoms or with aliphatic hydrocarbons, as they have one electron per C-atom left. But, on the other hand, we see that the same procedure which leads to the right order of magnitude of the heats of sublimation of the inert gases, hydrogen, oxygen, nitrogen, aliphatic hydrocarbons and the like, leads to the right value for the heat of sublimation of solid benzene.

In reply to a question by Dr. J. R. Katz: The distance of 10 Å. in polystyrene resulting from the X-ray investigations of Dr. Katz has puzzled me too. Perhaps it is related to a distance between two different polystyrene molecules in a special direction. In every case my steric formulae, supplementing the formula of Staudinger and based upon it, allow the distance of 10 Å. to the same extent as the formula of Staudinger does. There are no arguments in favour of the formula:—

In addition to the arguments in favour of the common formula:—

given above by Professor H. Staudinger, I mention the absorption spectrum\* of polystyrene which is identical to that of ethyl benzene.

The remark of Professor K. H. Meyer is very valuable; it shows that, as also in the case of the tensile strength, the experimental values found with cellulose fibre fit very well with the values given by theory.

# POLYMERS AND POLYFUNCTIONALITY.

BY WALLACE H. CAROTHERS.

*Received 12th July, 1935.*

## 1. Definitions.

The importance of polymerisations is indicated by the title of the present program, and it is a curious fact that little agreement exists concerning the accepted meaning of this term. Text-books, dictionaries, and even recent publications by original investigators,<sup>1</sup> generally state that a monomer and its polymer have identical compositions, and a corollary is that polymerisation consists in pure self-addition, and is peculiar to unsaturated compounds. But it appears that not one of these conditions is necessarily satisfied by reactions that are universally recognised to be polymerisations. Moreover there is little relation between actual usage and text-book definitions.

An accepted polymerisation is the transformation of formaldehyde into polyoxymethylene. The process under some conditions perhaps is

and under others <sup>2</sup>

In the latter case for moderately small values of  $x$  the composition of the polymer will be very different from that of formaldehyde: at large values of  $x$  the difference may be questionably detectable, but the question, of course, is one of fact not definition.

Turning to the mechanism of the process, there are various conceivable possibilities, such as:

1. The polymerisation of perfectly pure and dry formaldehyde might involve opening of the carbonyl bond giving free radicals  $-\text{CH}_2-\text{O}-$  whose mutual combination would result in a long chain.

2. In the presence of traces of water, we might have first

a manifestation of formaldehyde's very strong tendency to add ROH. The product here is also ROH, and reaction therefore proceeds

and further similar steps finally lead to a very long molecule.<sup>3</sup>

3. In aqueous solutions formaldehyde is largely present as hydrates

<sup>1</sup> E.g., Staudinger, *Die hochmolekularen organischen Verbindungen*, Julius Springer, Berlin, 1932, p. 10.

<sup>2</sup> Cf. Staudinger, *loc. cit.*, p. 255.

<sup>3</sup> Cf. Staudinger, *ref. 1*, p. 10.

Polymer is formed by adding strong acid to such solutions. The reaction might be

i.e., an intermolecular condensation or dehydration.

Further peculiarities are illustrated by polyesters where all of the following transformations can be realised in one case or another.<sup>4</sup>

In many cases the acid can be converted into a polyester under conditions where the monomeric lactone **C** is known to be stable. Moreover, it is then often possible by titration to show that a terminal carboxyl group is present in the ester product in the expected amount. The reaction involved is clearly one of condensation (not self-addition of an unsaturated or cyclic intermediate). Nevertheless, it seems scarcely reasonable or practical to argue that the product is not a polymer. For one thing, such polyesters can generally be transformed under appropriate conditions to the corresponding cyclic monomers (lactones), and the latter can be reconverted to products practically indistinguishable from **B**. In this case the reaction must consist essentially in self-addition. We can hardly say that a compound of the type **B** is a polymer if formed by one method, but not if formed by another. Moreover, there are some cases (e.g.,  $\delta$ -lactones and lactide) where transformation between **B** and **C** occurs so readily that it is difficult or impossible to know which one is the product first formed from the acid. Similar confusion occurs with many reactions involving formaldehyde: it is often impossible to know whether products arise by direct intermolecular dehydration of a methiolol compound or by self-addition of an intermediate methylene compound.

Further illustrations might be offered, but these perhaps are sufficient to show that: the composition of high polymers is not necessarily identical with that of the supposed parent monomers; polymerisations that appear superficially to involve only self-addition may involve preliminary hetero additions, and then actually proceed as condensations (or the reverse may be true); polymerisations are in any event not peculiar to unsaturated compounds (keeping in mind, for example, cyclic anhydrides, esters, acetals, and certain ethers and imines).

It is obvious that definitions need to be revised. It will not suffice to insist merely that usage is frequently wrong. The unfortunate effect of existing discrepancies becomes especially apparent when one reads that a resinification reaction (between an aldehyde and a phenol) doubtless proceeds through an unsaturated monomeric intermediate, because polymerisations are peculiar to unsaturated compounds.

Polymerisations are a special class of reactions, but just how are they distinguished from other intermolecular reactions? Conventionally, they involve the mutual combination of a number of similar molecules,

<sup>4</sup> Carothers, Dorrough, and Van Natta, *J. Am. Chem. Soc.*, 1932, **54**, 761; Carothers and Hill, *ibid.*, 1932, **54**, 1559; Hill and Carothers, *ibid.*, 1933, **55**, 5031, 5043; Spanagel and Carothers, *ibid.*, 1935, **57**, 929.

but this is not sufficient : the formation of diethyl ether is not polymerisation, and besides we already find references to mixed or hetero-polymerisations where the participating molecules are not all alike.

In the writer's opinion, the essential peculiarity of polymerisations is realised in the statement that they are intermolecular combinations (conventionally, self-combinations) that are functionally capable of proceeding indefinitely (or leading to molecules of infinite size). This may, in fact, be taken as a definition. By way of illustration, referring to the formaldehyde reactions outlined above, it is obvious that, regardless of which of the suggested mechanisms if any may be correct, the functional possibilities are such that any given number of formaldehyde molecules might be combined into a single molecule. The same possibility exists generally with

- (a) unsaturated compounds,
- (b) cyclic compounds and
- (c) polyfunctional compounds generally as, for example,  $x-R-y$  where  $x$  and  $y$  are capable of mutual reaction.

The compounds formally capable of polymerisation then are all polyfunctional compounds. Practically the functions must be such as to permit mutual combination, and polymerisation will then fail only in those relatively rare cases where reaction is exclusively intramolecular. A double bond or a reactive ring will count as a double function.

We may note then that polymerisations do not involve a single unique type of reactivity : they are for the most part merely ordinary reactions made manifold by polyfunctionality, and thus made capable of indefinite continuation in one, two, or three dimensions. But the functions and the mode of their action are generally the same as those already familiar in simple uni-functional compounds (though addition polymerisations of unsaturated compounds certainly present some special peculiarities).

## 2. The Peculiar Significance of Polymers ; Granular Polymers and Polymerisations in Living Organisms.

The most important peculiarity of high polymers is that they alone among organic materials manifest to a significant degree such mechanical properties as strength, elasticity, toughness, pliability, and hardness.<sup>5</sup> Weight for weight cellulose and silk are stronger than steel ; rubber exhibits a combined strength and elastic extensibility that is not even remotely approached by anything in the inorganic world while diamond is harder than any other material. The practical uses of high polymers depend almost entirely on these mechanical properties : our clothing and furniture and much of our shelter are made of such materials. The names cellulose, wool, rubber, and silk suggest at once the great importance of the non-chemical uses of natural high polymers.

Probably the bulk of the organic matter in living beings is made up of high polymers. The necessity for this lies in the fact that living organisms must have physical form and coherence, and polymers are the only organic materials capable of supplying these properties. The variability of living matter also requires a high degree of structural

<sup>5</sup> Cf. Meyer and Mark, *Der Aufbau der hochpolymeren organischen Naturstoffe*, Akademische Verlags gesellschaft, Leipzig, 1930.

complexity, and the possibilities of high polymers in this connection are indicated by Fischer's well-known calculation that 20 different amino acids may form  $2.3 \times 10^{18}$  different polypeptides of 20 units. Another pertinent fact is that the physical properties of high polymers are profoundly affected by their physical history: the melting-points of certain polyesters can be reduced several degrees by the mere application of stress and their strength in the direction of stress is at the same time increased many fold. Finally, reactions of polymerisation also appear to be uniquely adapted to the chemistry of vital growth because they are the only reactions that are capable of indefinite structural propagation in space.

Curious analogies with vital growth are found in granular polymerisations which have as yet received very little published attention, although a few observations on chloroprene in this connection have already been described.<sup>6</sup>

If we place a few grams of liquid chloroprene in the bottom of a long tube together with a little catechol to inhibit polymerisation, chill the tube, pump it out thoroughly and seal the top at the lamp, the tube may be allowed to stand upright for weeks without the appearance of any change. But if we concentrate a strong beam of light on a small spot at the top of the tube, a minute speck of white solid will appear within a short time. The light may then be removed: the speck will grow to a cauliflower-like mass at the expense of the vapours and thence of the liquid monomer until the latter is exhausted. The polymer on superficial inspection seems to be a mass of globules or cellular crystals, but X-ray examination reveals no crystalline pattern. The growth of the mass apparently occurs at different rates in different directions. Sometimes lateral growth is more vigorous than vertical, and the mass will then burst the walls of a very heavy tube, although the total volume of polymer is only a fraction of the available space. Any fragment of the granular mass when placed in fresh chloroprene liquid or vapour will act as seed around which further growth occurs. The viability of the mass as seed will usually persist on standing in laboratory air for several days, but finally it is lost. Similar observations can be made with butadiene and other materials. The analogies of this process with vital growth are obvious. The process may be labelled heterogeneous autocatalysis, but the mechanism of the catalytic effect is obscure. Reactive centres in the sense of free radicals are scarcely admissible, since the viability persists in air, and for various reasons neither adsorption nor solution seems to offer an adequate explanation.

Many different types of synthetic polymers can be made, but no naturally occurring polymerisation has yet been exactly simulated. Why should we not be able to synthesize cellulose, or proteins, or rubber? We can make innumerable members of each of these types: polyacetals, polyamides, and polyprenes. We can even make polyprenes that equal natural rubber in strength and elastic extensibility and are superior to it in many other respects, but the method (*i.e.*, the polymerisation of chloroprene) is as yet subject only to empirical methods of control and not to rational methods based on completely elucidated theoretical principles. Besides, this goal has not yet been approached starting from isoprene, and it is not at all certain that nature builds up rubber directly from isoprene: she might, for example, start with methyl-*n*-propyl

<sup>6</sup> Carothers, Williams, Collins and Kirby, *J. Am. Chem. Soc.*, 1931, **53**, 4214.

ketone and carry out a selective condensation polymerisation completely evading the diene intermediate.

The synthesis of proteins raises a different set of questions.  $\alpha$ -amino acids (or their esters) can be polymerised directly in vitro, but the product is usually the cyclic dimer (diketopiperazine). But in the organism, cyclisation apparently does not occur: reaction is exclusively intermolecular and a linear polyamide results. Generally speaking, cyclisation and chain formation represent two paths, the choice between which is determined almost completely by the nature of the initial reactant (especially its unit length).<sup>7</sup>

The conditions in vitro presumably are the normal ones of chance. If both reactions follow the same mechanism, we can say that in a compound of the type  $\text{NH}_2\text{CH}_2\text{CONHCH}_2\text{COOH}$ , intramolecular approach of the terminal groups is more frequent than intermolecular (which means cyclisation in vitro), but in the organism the probabilities are reversed and chain formation occurs. How can this be? Temperature and moderate dilution have small control over such matters, and perhaps then in the wrong direction. But if reaction is preceded by adsorption at an interface, as it might be biologically, the molecule is no longer free to assume its spatially probable configuration. Its head, tail, and middle are fastened to a surface and the only terminal approaches then possible may be intermolecular. This picture is not here proposed as a solution of the mechanism of protein synthesis: it is introduced rather as an interestingly conceivable possibility, but especially for the purpose of emphasising the following points: ring formation and chain formation are the two alternatively possible results of every bifunctional reaction; complete control over these alternatives is possible only by bringing the ends of the molecules together or separating them at will; the only apparent prospect of achieving this result lies in the use of surface forces; reactions in vivo probably occur largely at surfaces; and in any event the effect of surfaces on bifunctional reactions presents an almost completely unexplored field (except for the interesting preliminary work of Freundlich and of Salomon).<sup>8</sup>

### 3. Polyfunctionality.

Polymerisations generally may be divided into those that are bifunctional and those of higher orders. We may take an hydroxy acid as an example of the bifunctional type:

The two reacting molecules are monomers; the first product is a dimer, since it contains two structural units. At this point, half of the initial functional groups have disappeared; similarly, it is evident that the formation of two ester linkages (trimer) will involve 67 per cent. reaction, a tetramer will correspond with 75 per cent. reaction, etc. In general, if

<sup>7</sup> Carothers, *J. Am. Chem. Soc.*, 1920, **51**, 2548; Hill and Carothers, *ibid.*, 1933, **55**, 5023.

<sup>8</sup> *Helv. Chim. Acta*, 1934, **17**, 88.

$p$  is the degree (fraction) of reaction and  $\bar{x}$  is the average degree of polymerisation,

$$(1) \quad p = 1 - \frac{1}{\bar{x}}.$$

The following values are further illustrative :—

$p$	0	0.5	0.8	0.9	0.95	0.99	0.999
$\bar{x}$	1	2	5	10	20	100	1000

The average molecular weight rises very steeply with increasing degree of reaction beyond 0.95, and hence it is not impossible (as some authors maintain) to obtain very large molecules from condensation polymerisations. If  $p$  should reach one the molecular weight would become infinite.

As a hypothetical example of a more highly polyfunctional reaction, we may take an acid  $R(\text{COOH})_4$  and consider the result of intermolecular anhydride formation. We assume that the structure and conditions are such that no intramolecular reaction occurs at any stage. Representing the acid by  $A^4$  the anhydride would be

etc., where the superscripts indicate that each unit bears two unreacted carboxyls. Hence when all of the molecules have been combined into one (and no further intermolecular reaction therefore can occur) only 50 per cent. of the initially present functional groups have disappeared, *i.e.*,  $p = 0.5$ . The formation of branching chains of course does not affect this conclusion.

A general equation relating degree of reaction, polymerisation, and functionality can be developed.

Let  $f$  = degree of functionality (*i.e.*, number of functional groups per monomer molecule).

$N_0$  = number of monomer molecules initially present.

Then  $N_0 \cdot f$  = number of functions initially present.

$N$  = number of molecules after reaction has occurred.

$2(N_0 - N)$  = number of functions lost.

$\frac{2(N_0 - N)}{N_0 \cdot f}$  = fraction of functions lost =  $p$  = extent of reaction.

Obviously,  $\frac{N_0}{N} = \text{average degree of polymerisation} = \bar{x}$ .

Hence

$$(2) \quad \frac{2}{f} - \frac{2}{\bar{x} \cdot f} = p = \text{degree of reaction}.$$

This equation has interesting applications. If we heat together a dibasic acid and a glycol, a linear polyester is formed. As the reaction, measured by the disappearance of acid progresses, the average molecular weight rises, presumably in accordance with equation (2). Reaction becomes exceedingly slow after it is 99 per cent. complete, and the calculated molecular weight approaches 15,000 to 20,000. But no matter how far the reaction is carried under normal conditions, the product is both fusible and soluble.

If in a similar manner a dibasic acid is heated with glycerol, one observes at first that the viscosity of the mixture changes only slowly as reaction proceeds, and then it rises to infinity while much of the acid

remains still unreacted. The product is completely infusible and insoluble.

Obviously, bifunctional reactions can yield only linear polymers; and there is evidence among such polymers that solubility and fusibility are not lost even at very high molecular weights. But reactions of higher orders always present the possibility of spreading out in three dimensions.

Returning to the anhydride symbolised above as

let us suppose that the chain is 100 units long, and bears 200 carboxyl groups. Such a molecule could easily be soluble and fusible. If further intermolecular reaction occurs, the chain must become cross-linked. Obviously, when 2 carboxyls have been lost from each chain, all the chains will be locked into a single molecule. This involves the loss of 1 per cent. of the remaining carboxyls: and it will certainly be accompanied by the disappearance of fusibility and solubility: a gram of matter cannot exhibit the kinetic behaviour of a single molecule.

Referring again to formula (2) if  $x$  is very large the second term disappears, and we have  $p = 2/f$  which tells at what degree of reaction the molecular weight will become infinite, or where, in polyfunctional reactions, gelation will occur and intermolecular reaction cease.

For a bifunctional reaction  $p = \frac{2}{f} = 1$ , and since this value never can actually be reached, gelation will not occur. For a trifunctional reaction, the limit will lie at  $p = \frac{2}{3}$ , for a tetrafunctional reaction at  $\frac{1}{2}$ . We may note in passing that for this reaction at  $x = 100$ ,  $p = 49.5$  per cent.; thus the average molecular weight will suddenly change from a moderate to a colossal value with very little change in the extent of reaction: and so far as the utility of the formula is concerned, it is not important whether the transition in properties occurs at a molecular weight of  $10^5$  or  $10^{20}$ .

In attempting to apply formula (2) the chemistry of the situation must, of course, be taken into account. A double bond will count as a double function only if reaction is exclusively intermolecular at every stage. Multiple function compounds often do not exercise all their functions together. In the formation of polyprenes from dienes, only the 1, 4-positions of the latter are at first called into play. The remaining double bond of each unit functions under slightly different conditions to cause cross-linking. Acetylene would be a tetra-functional compound and probably behaves as such in the formation of cuprene. In the formation of divinyl acetylene,<sup>9</sup>  $\text{CH}_2=\text{CH}-\text{C}\equiv\text{C}-\text{CH}=\text{CH}_2$ , only half of its unsaturation is involved. This material again in the early stages of its thermal polymerisation behaves like a bifunctional compound yielding, for example,<sup>10</sup>

but gelation usually occurs long before all of the divinyl acetylene has reacted.

<sup>9</sup> Nieuwland, Calcott, Downing and Carter, *J. Am. Chem. Soc.*, 1931, **53**, 4197.

<sup>10</sup> Cupery and Carothers, *J. Am. Chem. Soc.*, 1934, **56**, 1167.

Perhaps a majority of the reactions to which equation (2) would be applied are of the A—B type involving two reactants of complementary function. It is evident that if each reactant is bifunctional,  $A^2B^2$ , the reaction as a whole will be in effect bifunctional:  $A^3B^3$  is trifunctional, etc. But if A and B have a different number of equivalents per molecule, the situation is more complicated. We can distinguish two different possibilities :

(a) Suppose that on the average every coupled molecule of A involves also the coupling of an equivalent number of molecules of B ; then the degree of functionality is the average number of functions per molecule of the two reactants when they are taken in equivalent amount. Thus in the reaction of glycerol and phthalic anhydride ( $A^3B^2$ ) we have to take 2 moles of glycerol and 3 of the acid, or 5 altogether, containing 12 equivalents and  $f = \frac{12}{5} = 2.4$ . Then at  $x = \infty$ ,  $p = \frac{2}{2.4}$  and the limit of the reaction will be  $\frac{2}{3}$  (83.3 per cent.). This, in fact, represents the *maximum* amount of reaction that can occur before gelation under any distribution of combinations, provided only, of course, that the reaction is all intermolecular.<sup>11</sup>

(b) Another extreme possibility is the following : Suppose the glycerol behaves at first as though it were bifunctional yielding a chain

( ' indicates unreacted hydroxyl). Then all of the molecules of glycerol could be combined into one with the loss of only  $\frac{2}{3}$  of the functional groups (of course  $\frac{1}{3}$  of the phthalic anhydride remains entirely unreacted). Here  $f = 3$  and 66.7 per cent. is the minimum extent of reaction compatible with gelation. Experimental values found by various investigators for the extent of reaction at gelation generally lie between 75 and 80 per cent.<sup>12</sup>

Reactions of polymerisation involving degrees of functionality running into the hundreds or thousands are undoubtedly of great importance. The vulcanisation of rubber is an example. The preponderance of evidence lies in favour of the view that vulcanisation is the result of cross-linking through reaction at the double bonds. A conservative estimate of the number of double bonds in the average rubber molecule is 5000. Suppose the mechanism of vulcanisation is as follows : At some double bond  $:C=C: + S \longrightarrow :C - C:$ . Sulphides of this struc-

ture are known to be unstable, and further reaction might occur with a similar group in a neighbouring molecule,

<sup>11</sup> A similar calculation for the glyptal reaction has already been made by Bozza, *Giorn. chim. ind. applicata*, 1932, 14, 400.

<sup>12</sup> Bozza, *loc. cit.*<sup>11</sup>; Kienle and Hovey, *J. Am. Chem. Soc.*, 1929, 51, 509.

At a minimum then all the rubber molecules could be locked together when only 0.04 per cent. of the double bonds had disappeared, or about 0.02 per cent. by weight of sulphur had reacted. A good estimate for a probable maximum is difficult to make. Experimentally, the minimum amount of sulphur required for the beginning of vulcanisation<sup>13</sup> is about 0.15 per cent. Staudinger and Heuer have shown<sup>14</sup> that as little as 0.01 per cent. of divinyl benzene in styrene will lead to the formation of an insoluble polymer.

#### 4. Molecular Weights and Molecular Weight Distributions.

The peculiarities of high polymers are due to the fact that their molecules are very large. Estimates of molecular weights are therefore of the utmost importance, but they are very difficult to obtain. Direct osmotic methods present great practical difficulties. Staudinger has proposed to infer molecular weights from the viscosities of polymer solutions. There appears to be no doubt that, other things being equal, the viscosity of such solutions will increase with increasing molecular weight, and viscosity methods are unquestionably of great value as a means of providing rough estimates concerning the relative order of magnitude of molecular weights in a given polymeric series. But the absolute values inferred from viscosities are subject to a very large factor of uncertainty. An initial difficulty lies in the fact that no generally valid relation between viscosity and concentration in solutions of linear polymers has yet been established. Presumably some simple and general relation will be found to exist in solutions that are sufficiently dilute but possibly only at dilutions requiring a higher degree of experimental precision than is now generally available. (In theory, of course, extrapolation to infinite dilution is always possible, but practically such extrapolations may also involve large uncertainties.)

Aside from this point, there is one theoretical complication that has as yet received relatively little attention. High polymers are generally mixtures covering a wide range of molecular species. The properties of a polymeric mixture will depend not only upon the average molecular weight, but on the manner in which the different molecular species are distributed about the average. Moreover, as Kraemer and Lansing<sup>15</sup> have recently shown, it is possible to define various types of averages :

specifically, for example, there are the number average  $M_n = 1/\sum \frac{f_i}{M_i}$ , and the weight average  $M_w = \sum f_i M_i$ , where  $f_i$  is the fractional weight of the constituent of molecular weight  $M_i$  in the mixture, and the summation is applied to all the constituents. The number average is the conventional one: it is this that is inferred from osmotic methods or chemical measurements of end groups. But all the proposed viscosity relations would give  $M_w$ .

If a material is homogeneous,  $M_n$  and  $M_w$  will be identical: but if we are dealing with a mixture they will generally be different. If we have 10 molecules of weight 100 and 5 of 1000,  $M_n$  is 400 but  $M_w$  is 851. Thus a correlating factor for molecular weight vs. viscosity arrived at by

<sup>13</sup> Bruni, *Rev. gen. Caoutchouc*, 1931, 8, No. 75, 19; Stevens and Stevens, *J. Soc. Chem. Ind.*, 1932, 51, 44T.

<sup>14</sup> *Rev.*, 1934, 67, 1164. See also *ibid.*, 1935, 68, 1618.

<sup>15</sup> *J. Physic. Chem.*, 1935, 39, 165; *J. Am. Chem. Soc.*, 1935, 57, 1369. See also Kern, *Ber.*, 1935, 68, 1439, and Staudinger, *Helv. Chim. Acta*, 1929, 12, 941.

observations on a homogeneous material is almost certain to give erroneous values when applied to a polymer. And unless the type (distribution) of heterogeneity in all polymers is nearly the same, there cannot possibly be any exact generally applicable correlation between viscosity and molecular weight.

As Kraemer and Lansing have pointed out, the Svedberg ultracentrifuge provides the only means yet available for determining experimentally both the average molecular weight and the distribution in polymeric mixtures. But this method is not simple, and the apparatus is very costly, and hence experimental data are as yet extremely meagre.

It is therefore a matter of considerable interest to make calculations as to the theoretically probable distribution of molecular species in polymerisation reactions. Such calculations have been made by Dr. P. J. Flory<sup>16</sup> of this Laboratory, and it may be worth while to give a brief indication of some of the results.

The simplest case is the formation of a linear condensation polymer. Here we have a series of stepwise reactions

always involving the same functional groups. Whatever may be the general effect of viscosity on reaction rate, the inherent relative reactivity of a functional group will presumably be but little affected by the length of the molecule to which it is attached. If this assumption is correct, it is possible to show that

$$\Pi_x = xp^{x-1}(1-p)^2,$$

where  $p$  is the extent of reaction and  $\Pi_x$  is the fraction of units present in  $x$ -mers (which also equals very nearly, except for low values of  $p$ , the weight fraction of  $x$ -mer).

In Fig. 1,  $\Pi_x$  is plotted against  $x$  for various values of  $p$ . It is evident

<sup>16</sup> Unpublished results.

that we are dealing with a wide distribution of species. Certain relations are most briefly shown by means of an example.

If we assume that the weight of the mer or unit is 100, and reaction has been carried to 98 per cent. of completion ( $p = 0.98$ ), then  $M_n$ , the number average molecular weight is 5000, and the maximum in the distribution curve also occurs at this point. But the nature of the curve is such that only 26 per cent. by weight of the material has a molecular weight below 5000, while 74 per cent. has a weight at or above 5000. Moreover, 40 per cent. of the material has a molecular weight above 10,000. Finally, the weight average molecular weight is 9900 or nearly twice the number average.

Mechanical properties, such as toughness and tensile strength, certainly require the presence of very large molecules. But it is not at all certain that these properties will be improved by the elimination from a material of all fractions having low or moderately high molecular weights. In rubber and cellulose plastics the deliberate addition of small foreign molecules (plasticisers, lubricants, etc.) often has a very favourable effect on properties. It is probable that average molecular weights *per se* will furnish an entirely inadequate basis for the interpretation of those properties which are chiefly of interest in dealing with high polymers. The study of molecular weight distributions and their relation to properties thus presents a field which should ultimately be of great importance to the subject of polymerisation.

### GENERAL DISCUSSION

Professor R. Signer (Bern) said: Carothers concludes that, in order to establish the properties of a highly polymerised substance, we must take into account not only the mean molecular dimension but also the molecular weight distribution. He suggests that polydispersity may chiefly be established by the use of the Svedberg ultra-centrifuge, but adds that it is essential that the experimental data are as yet extremely meagre. In this connection we observe that recently<sup>17</sup> R. Signer and H. Gross in Svedberg's laboratory conducted extensive experiments on the molecular weight distribution of polystyrenes. It appears that determinations of polydispersity by measurement of sedimentation velocity can only be effected in extremely dilute solutions. At large concentrations the fibre molecules are entangled or matted, so that, whether short or long, they move with equal velocity. It is also essential to use very intense centrifugal fields; the sedimentation process must be carried out so rapidly that the diffusion of the fibre molecules can be neglected. With Svedberg's apparatus both these conditions may readily be fulfilled.

Dr. R. Houwink (Eindhoven) said: Formula (2) is only applicable to bifunctional reactions. It seems very questionable whether it can be applied to polyfunctional reactions, as will be seen from Fig. 1. As soon as the two polymers, A and B, have reacted at the spots 1 and 4, each further reaction, *e.g.*, between spots 2 and 5, or between spots 3 and 6,

FIG. 1.—The functional groups are indicated by x.

<sup>17</sup> *Helv. Chim. Acta*, 1934, 17, 726.

will result in a further decrease of the number of functions, *whereas no change in  $N$  or  $N_0$  takes place*. It does not therefore seem justified to say in such a case that the number of functions lost is  $2(N_0 - N)$ . Since formula (2) has been developed on such a basis, however, that formula cannot be right.

**Dr. H. B. Weiser** (*Houston, Texas*) said: If the term molecular weights is to continue to have any real significance, it should be restricted to its time-honoured use. In the colloidal systems under consideration to-day, the particles are in many cases aggregates of polymerised molecules, and not individual polymerised molecules. If the size-distribution in such systems is more or less uniform, determinations may be made of the so-called "molecular weights" by sedimentation methods. But in the case of aggregates it is the "particle weights" and not the molecular weights which is obtained by such methods. Using Zsigmondy's nuclear procedure, a large number of samples of colloidal gold may be prepared in varying particle size from extremely minute to relatively large. But in each sample the particle size is approximately uniform. Gold, therefore, may be made to have any "particle weights" one pleases within rather wide limits. It seems absurd to say that gold has any number of molecular weights. Irrespective of whether we are dealing with relatively simple inorganic systems or with highly polymersed organic systems, it is suggested that the term "molecular weights" be applied only in its original sense when the evidence indicates that we are working with the individual molecules; and that the term "particle weight" be used *in cases of doubts*, or where the particles are known to consist of aggregates of molecules.

**Professor K. H. Meyer** (*Genève*) said: Dr. Carothers has spoken of the polymerisation of amino-acids, which *in vitro* give the cyclic dimer, and *in vivo* build up the long protein chains. He spoke of the possibility of polymerisation *in vivo* taking place on interfaces and being influenced and directed by fields of force in the cellular interfaces. I do not think that one ought to attribute this effect to the interfacial forces, which seem to be greatly over estimated by biologists. The interfacial forces in the organism must be somewhat small, owing to the presence of so many substances with interfacial activity, which lower the tension at the interfaces and reduce the interfacial forces. The forces in the cell interfaces cannot be compared with the forces at a carbon surface, but at the most with the forces in an oil-water interface.

It seems safe to assume that the organism uses indirect chemical ways to guide reactions. It may be of interest, that a derivative of amino-acids, the cyclic anhydride discovered by Leuchs,<sup>18</sup>

is readily transformed into polypeptides of very high molecular weight, with liberation of carbon dioxide.<sup>19</sup> We think that the organism may form the long chains by similar means.

<sup>18</sup> *Ber.*, 1906, **39**, 857; 1908, **41**, 1721.

<sup>19</sup> K. H. Meyer and J. Go, *Helv. Chim. acta*, 1934, **17**, 1488.

**Professor H. Mark** (*Wien*) said: Dr. Carothers' results, especially those in Fig. 1, where one finds the distribution of chainlength at different stages of reaction, are most interesting. The formula which leads to this figure is derived under certain suppositions. First, it was assumed that the chain may be built not only by addition of the saturated monomeric molecule, but also by mutual additions of chains, which have already reached a certain length. In fact, it is very likely that both kinds of reaction take place; but it seems rather improbable that the rates of these two reactions are also equal.

In any event, knowledge of the chain distribution at a given stage of polymerisation is of the greatest interest for the mechanism of reactions of this kind, and it is very important to have as many methods as possible to work out such a distribution curve experimentally. So far, this has only been accomplished in the well-known work of Signer on polystyrene by means of Svedberg's ultracentrifuge. Dr. Carothers has a very extensive experience in dealing with high molecular substances; does he know any other reliable method, whereby one could work out a distribution curve of the type shown in Fig. 1. This seems to be especially important, because the ultracentrifuge is a very expensive and complicated apparatus, which only exists in two different places in the world.

I would like to add, that there is some possibility of estimating the distribution of chains, if one takes in account the different average types in determining the molecular weight of high molecular substances from the viscosity and from the osmotic pressure; these Carothers calls "number average"  $M_n$  and "weight average"  $M_w$ . When the two methods lead to different results, there must be a rather remarkable difference in the length of the chains, contained in the sample.

**Professor H. Staudinger** (*Freiburg i. Br.*) said: Among the high molecular organic compounds, *i.e.*, the compounds which are built up of macromolecules, high polymers are of particular importance. Having regard especially to the different new experimental procedures in this field it is necessary to discuss the question of the nomenclature of these substances.

All high molecular weight products consist of macromolecules of such size that the physical and chemical properties of molecules of approximately equal structure and equal size differ so little that a mixture of these cannot be separated into their components. The high polymeric materials consist of *macromolecules* which represent a mixture of *polymeric homologous compounds*, *i.e.*, a mixture of macromolecules which differ only in the degree of polymerisation. Hence, high polymeric materials are built up from one and the same basic molecule ("*Grundmolekül*") in such a way that numerous basic molecules are combined by primary valency bonds to form the macromolecules. In the case of heteropolymers, not only one but several different basic molecules participate in the building up of the high polymeric macromolecule. The mixed polymers of styrene and maleic anhydride, etc., are heteropolymers.<sup>20</sup> Furthermore, the polyesters may be considered as heteropolymers, since in their macromolecules several basic units are combined in the same way. Thus, the polyesters obtained from succinic acid and glycol are built up of succinic anhydride and ethylene oxide. The above polymers, with the exception of molecules which are rings of high molecular weight are, strictly speaking, not real high polymers, since the end groups of such molecules are built up in a different manner from the chain, in which the atomic arrangement of the basic unit is repeated regularly.<sup>21</sup>

High polymeric materials can be formed in different ways. First, they

<sup>20</sup> Wagner-Zauregg, *Ber.*, 1930, **63**, 3213.

<sup>21</sup> In this case also it is possible that the arrangement of the basic molecules in the chain is not regular, as is observed with polyoxymethylene. (Compare *Liebigs Annalen*, 1929, **474**, 232).

can arise by polymerisation of unsaturated compounds. In this case, as has been pointed out in contribution No. 6,<sup>22</sup> one can discriminate between *true polymerisation processes* and *condensation polymerisation processes*. In true polymerisations the polymeric molecules possess the same atomic arrangement as is present in the basic molecule. In the condensation polymerisations, on the other hand, a shifting of atoms, e.g., hydrogen atoms, takes place. High polymeric products can also arise from low molecular ring systems. Ethylene oxide can be transformed into polyethylene oxide, lactones into polyesters. Finally, the formation of high polymeric products can also take place by a *polycondensation* process in which numerous reactive molecules condense. Thus, the polyesters are formed from the esters of hydroxy acids by intermolecular esterification of numerous single molecules through loss of water, i.e., by a process which cannot be designated as a polymerisation process, if one maintains for the latter the old definition. Following this definition, a *polymerisation process* is a process in which a substance of low molecular weight is transformed into a substance of equal composition but of higher multiple molecular weight. Hence, polyesters should best be designated as *polycondensation products*, if one wishes to characterise their manner of formation.

These questions of nomenclature may be further illustrated in the case of cellulose. This high molecular substance may be designated as "high polymeric," since the cellulose molecule is built up of numerous similar basic molecules of glucose anhydride. However, if one wishes to emphasise the building up of cellulose from glucose or cellobiose, then cellulose is a polycondensation product of these saccharides. In the case of many high molecular substances there are special reasons which decide whether they ought to be considered as polymerisation or polycondensation products. The phenol formaldehyde resins, e.g., "bakelite," can be designated as polycondensation products, since it is not certain that one and the same structural unit occurs regularly in the three-dimensional macromolecules of the resin.

**Dr. R. Houwink (Eindhoven)** said: Is it the intention of Dr. Carothers to distinguish in future between "polymerisations" and "condensations" as heretofore? Will the new definition of "condensations" then be: intermolecular combinations which are functionally capable of proceeding indefinitely with the elimination of elements or simple compounds?

**Dr. W. H. Carothers (Wilmington)**, said, in reply to Dr. Houwink: The application of formula 2 to the calculation of molecular size naturally involves uncertainty, since it depends upon the arbitrary assumption that reaction is *exclusively* inter-molecular. This condition surely is not exactly fulfilled, especially in highly polyfunctional reactions where the calculated molecular weight is rapidly approaching infinity. The approximate validity of this assumption has, however, been demonstrated experimentally in appropriate simple cases, and its use for illustrative purposes seems to be well justified.

*In reply to Dr. Weiser*: The question of the relation between molecular weight and particle size is, I think, in many cases not capable of any simple solution, but for the simpler types of organic polymers it is possible to assign a definite and rather exact significance to the term molecule (as Professor Staudinger has done) and to demonstrate by chemical means that the chemical molecule is the osmotic particle under consideration.

*In reply to Dr. Meyer*: The N-carboxy-anhydrides of the  $\alpha$ -amino-acids discovered by Leuchs are indeed compounds of great interest. Attention has already been drawn to the possibility that they may constitute intermediates in the protein synthesis. From this standpoint they are compounds that certainly deserve a great deal more study.

*In reply to Dr. Mark*: Unfortunately, I am not aware of any chemical method for determining molecular weight distributions. Apparently the

<sup>22</sup> Compare also H. Staudinger, *Ber.*, 1920, **53**, 1081.

only method yet available is that of the ultra-centrifuge, which, in connection with lyophilic polymers, has lately been used for this purpose by Lansing and Kraemer and by Signer.

Professor Staudinger's point of view has considerable historical justification, but it presents certain logical and practical difficulties. Apparently it involves the necessity of making a distinction between polymers and "real polymers" and of admitting that polymers can be formed by reactions that are not polymerisation.

The essential point of the conventional definition is that a monomer and its polymer have exactly the same composition. But this condition is not in fact satisfied in many of the cases to which the name polymer has become firmly attached. Professor Staudinger was himself the first clearly to recognise this in the case of the polyoxymethylenes. Nevertheless he still refers to them as polymers and only occasionally adds that they are not so, strictly speaking. The determination of composition with sufficient precision to demonstrate the absence of foreign terminal groups in very long molecules is experimentally very difficult. It is possible that among such materials no "polymers strictly speaking," exist. But it is one of the aims of scientific terminology to permit one always to speak strictly, and this becomes impossible if definitions are formulated to include conditions that are not open to experimental test.

As a matter of actual fact, chemists use the terms polymerisation and polymer without pretending to wait for evidence that reactions consist in pure self-addition, or that the condition of identical composition is satisfied. Thus, by implication it seems to be recognised generally that the characteristic and peculiar feature of polymerisations resides in something not compatible with the conventional definitions. The statements offered in the first section of the above paper constitute an attempt to indicate what is this characteristic and peculiar feature.

In connection with Dr. Rideal's interesting survey of the general field, I should like to raise one point. The term "linear polymer" was, I believe, first introduced in 1929. It was explicitly intended to include both open and closed chains. The necessity for this arises from the fact that the terminal groups may, in many cases be undetectable, even when they are present, and it is unwise to include in a definition any conditions that are not subject to experimental test.

It is true that large molecules are in some cases built up from small ones by reactions that appear, at least, to consist in pure addition, while in other cases they are formed by reactions that are demonstrably condensations. Staudinger proposes to call the latter type of reaction polycondensation (as Chalmers has also). This seems an appropriate term (perhaps it is better than condensation polymerisation which Staudinger prefers to use for another purpose), but I contend that we may as well give in to the logic of the situation and admit that such reactions constitute one type of polymerisation: the products are polymers (Staudinger himself calls them such in his remarks above). Besides they can in many cases be smoothly depolymerised to the corresponding cyclic monomers, and reversal of this process then yields a product which is often indistinguishable from the original polycondensation product. (These last remarks are also offered in reply to Dr. Houwink's second question.)

# THE MECHANISM OF POLYMERISATION.

BY H. DOSTAL AND H. MARK (Wien).

Received in German 22nd July, 1935, and translated by  
Dr. G. RABINOWITSCH.

A certain number of polymerisation-processes—especially some organic reactions of this kind—were thoroughly investigated many years ago.<sup>1</sup> They owed this early interest to the fact that the products which they yield have some unusual properties, interesting from the point of view of pure science—and sometimes from that of industry as well. For a long time uncertainty prevailed about the kind of molecules of which these substances are composed, ordinary methods of molecular weight determination failing to give an answer to this question.<sup>2</sup> The insolubility and extremely low vapour-pressure of the polymeric substances make it impossible to determine their molecular weight in the gas-phase or in the state of dilute solution, and the size of their molecules can only be estimated by other, less reliable methods.<sup>3</sup> In the course of years, however, a conception arose, which presumed the substances in question to be built up of long chain-molecules. The exact length of the chains is supposed to depend on special conditions of polymerisation, but to be generally very great as compared with that of ordinary molecules. Methods have been devised for the determination—at least approximately—of the molecular weight of such chain-molecules. The first qualitative investigations of the polymerisation-reactions are due to Anschütz, Auwers, Harries, Ostromysslensky, Willstätter and others.<sup>4</sup> Latterly, this field has been systematically investigated by H. Staudinger and W. Carothers. In his well-known monograph *Über die hochmolekularen Verbindungen*, Staudinger<sup>5</sup> collected a vast amount of material concerning the preparation and properties of these substances. Together with other investigators, he showed convincingly that polymerisations really yield products with long chain-molecules and a molecular weight up to many thousands. Analogous results have been obtained by Carothers,<sup>7</sup> R. O. Herzog, K. Freudenberg, K. H. Meyer, H. Mark, and others, so that the chain-structure of the polymerisation products can now be considered as a fairly well-established fact.<sup>6</sup> The experiments showed, however, that polymerisation-products are not chemically pure substances; in the sense that all their molecules are not exactly

<sup>8</sup> A different view is held by K. Hess, *Lehrbuch der Cellulosechemie*, 1928.

identical. The chains are all built up on the same principle, but with a different actual number of chain-links. Besides polymers of this kind, some polymerisations give products with properties indicating a two-dimensional net-structure or a three-dimensional lattice rather than one-dimensional chains. Probably, in these cases, the chains which are at first formed are linked together in two or three dimensions by valency-forces. So far, however, it has not been possible to state definitely the mean size (or the distribution of sizes) of the molecules in such more complicated cases of polymerisation—as was found to be possible in the simpler case of "one-dimensional" structures.

Considering the great amount of experimental evidence which has been collected in the endeavour to elucidate the nature and properties of the long chain-molecules, we think it timely to discuss more in detail the mechanism of the reactions by which chain-molecules are formed.<sup>9</sup>

In this paper, we shall first give a short summary of the work already done in this direction and then try to bring forward some points of view of our own. The object of our discussion will be the *polymerisation* of unsaturated organic molecules (with double or triple bonds)—*i.e.* of molecules which are able to form chains by simple addition. We will thus postpone to a later occasion the discussion of so-called *condensations*, —*i.e.* reactions in which the original molecules are saturated and lose a constituent part (for instance,  $H_2O$ ,  $NH_3$ , etc.) in order to form a chain.

### 1. Experimental Results.

Whereas preparative investigations of the polymerisation-reactions have been very numerous, only few of them contain any observations concerning the kinetics of the polymerisation-process at all. As far as data of this kind can be found, they usually refer to a single preparation and are not a result of a systematic kinetic investigation.<sup>10</sup> This lack of experimental material is probably due to the fact, that measurements of the velocity of polymerisation are by no means simple and require special precautions. It is, in fact, well known that the velocity of many reactions of this kind is strongly diminished by the presence of minute traces of certain foreign substances. We shall show later that these substances act as "anticatalysts." The industry is well aware of this effect and uses substances of this kind as "stabilisers" for certain technical products. The stabilisers probably reduce the velocity of polymerisation by breaking reaction-chains. On the other hand, substances are known, which enormously accelerate the velocity of polymerisations, even when present in a very small concentration. Such is, for instance, the action of sodium on butadiene, of oxygen on  $\beta$  chlorobutadiene, and of iodine on vinyl ether. These "positive" catalysts probably favour the formation of "nuclei," which are starting-points of further polymerisation. The occurrence of positive and of negative catalysis can in fact be considered as a typical feature of polymerisation reactions. This fact provides some useful hints towards the understanding of the mechanism of the reactions in question; but, on the other hand, it makes exact experimental treatment of the problem rather difficult.

Table I. gives a summary of the most important data concerning the

<sup>9</sup> Compare W. Chalmers, *Canad. J. Res.*, 1932, 7, 113.

<sup>10</sup> For instance, Staudinger and Suter, Whitby and Crozier, Whitby and Katz, and others.

velocity of thermal polymerisation reactions. One sees how scarce is the material available in the literature of the subject. Seldom has the reaction velocity been studied over sufficiently long time-intervals and at different temperatures. Most of the investigations have been carried through with polymerising substances in the pure liquid state, whereas investigations of more or less dilute solutions would give results much easier to interpret. If the best experimental results available are plotted in the form of graphs, reaction-curves of the type shown in Figs. 5 to 8 (p. 17) are obtained. W. Chalmers<sup>11</sup> suggested that polymerisation reactions are "quasi-monomolecular," column 5 of Table I. shows that this conception is not without foundation.

True, the velocity-constants, calculated as for a monomolecular reaction, show variations up to 50 per cent. of their mean value; but—in some cases at least—there is no definite trend, and the irregular variations may therefore be ascribed to experimental errors. However, a more detailed analysis of the reaction-mechanism leads us to a much more complicated kinetic law. Our task will be to test this law by comparing its predictions with experimental results.

<sup>11</sup> Compare also W. Chalmers, *J. Amer. Chem. Soc.*, 1934, 56, 917.

Recently, systematic investigations of the polymerisation of styrene and of acryl ester at different temperatures have been started with pure liquids as well as with solutions. Some results of these experiments are given in Figs. 5 and 5a. We recognise a short "induction" period, followed by a long interval in which the polymerisation-velocity remains constant. Finally, as the polymerisation is nearly completed the reaction velocity slows down, and the system approaches asymptotically the limiting state of complete polymerisation.

This behaviour is especially clear in the case of styrene, which has been thoroughly investigated by Raff and Iorde. These experiments form the foundation of our further theoretical discussions. We intend to show that satisfactory accordance between theory and experiment can be obtained on the assumption that the polymerisation is a two-stage process.<sup>12</sup> The first stage is the formation of "nuclei," for instance, by collisions between two monomeric molecules. This stage requires an activation, which can be a thermal, photochemical or catalytic one; it can occur mono- or bi-molecularly. In the next section of this paper, formulae will be developed for all these special cases.

In the cases of thermal polymerisation of the ethylene derivatives, especially of styrene, of the vinyl esters and vinyl chlorides, of the acryl esters, etc., experiments indicate a thermal, bimolecular mechanism of the formation of nuclei. When two styrene molecules meet with sufficiently high energy, the two double bonds are "opened" and doubly unsaturated dimeric radicals can be formed, of one of the following kinds:

either:

or:

We may consider the formation of a nucleus, in a case such as this, as an ordinary bimolecular process, with a collision-factor of the usual order of magnitude, and an activation-energy of 30-50 cal. per mol. An analogous explanation can be supposed to hold for the polymerisations of other ethylene-derivatives, so long as reactions in the dark and without catalysts are alone concerned.

The cause of the inability of ethylene itself to polymerise must be sought in a higher stability of its double bond, which is loosened by substituents. This assumption accords with the general difference in the chemical properties of ethylene and of its derivatives. The dipole structure of the derivatives may contribute to the acceleration of the reaction by which polymerisation nuclei are formed, because dipole molecules possess stronger van der Waals' attractions and come, therefore, into closer touch during collisions.

In the case of *photochemical* polymerisations (for instance, of acrylic esters, of butadiene, etc.) we can expect nuclei to be formed according to a monomolecular law. The monomeric molecule is activated by absorption of light, so as to be able to form a nucleus when colliding with an ordinary non-active molecule. In the next section, formulae referring to this case will also be given.

Very often polymerisations are caused by *catalysts*, as, for instance, by sodium in the case of butadiene, or by oxygen in that of butadiene-chloride.<sup>13</sup> Important investigations by Ziegler<sup>14</sup> proved, that sodium

<sup>12</sup> Compare also W. Chalmers.<sup>9</sup>

<sup>13</sup> Compare e.g., Ziegler and Bahr, *Ber.*, 1928, 61, 254; *Lieb. Ann.*, 1929, 473,

<sup>14</sup> See W. Carothers, *loc. cit.*<sup>7</sup>

and other alkaline metals increase the velocity of formation of polymerisation nuclei by "adsorption" on the double bonds. Oxygen acts in the same way in the polymerisation of chloroprene, as Carothers found in the course of his extensive investigations. Because of the complications which may occur in cases of catalytic polymerisation, we shall at first exclude them from our discussion. It would be relatively easy to introduce catalytic effects into our formulae, if only these effects could be restricted to the velocity of formation of the nuclei.

The formation of nuclei may be considered as the first necessary step of every polymerisation process. Its result is the production of a number of activated molecules or reactive radicals.

There are essentially different ways in which these molecules or radicals may further react.

(1) The nucleus may collide with a second monomeric molecule of the initial substance, combine with it and *grow* in this way. The unsaturated character of the one of the collision partners leads us to expect a somewhat low activation energy for this reaction, and the velocity of chain growth can therefore be high as compared with the velocity of the formation of nuclei. The formulae given below show that the formation of a relatively large number of short chains or of a smaller number of long chains depends on the relation between the velocity of formation of nuclei and that of the chain-growth. If the absolute values and the dependence on temperature of both these velocities are known, the whole process is quantitatively described by our equations—with the exception of some side-reactions which will be discussed later. The results of many investigations—especially by Bonhoeffer, Hinshelwood, and Polanyi<sup>15</sup> showed that the activation-energy of chain-growing reactions is usually of the order of 5 Cal. per mol only, which means a very high reaction-velocity indeed. It is, however, to be remembered that, as soon as the molecules become long enough, the collision-factor cannot be expected to be the same as it was before. The reactivity of the active ends of the chain may be inhibited by other parts of the large molecule. In general, we may expect the "sensitive" region of a chain molecule to become smaller with growing length of the chain, despite the fact that the molecule still bears on its ends the same unsaturated radicals. This effect can be taken into consideration in developing the formulae; but we shall disregard it at first, and consider the velocity of chain growth to be a constant, dependent only on temperature and not on the length of the chains.

(2) The repeated addition of monomeric molecules is not the only way in which the nuclei may react; there exists a number of other possibilities. The simple picture of the polymerisation process, which was given above (and which has been also discussed before) becomes complicated by these additional possibilities; but only by their full consideration is the theoretical scheme adequate to describe the great variety of the experimental results.

(a) Firstly, let us consider the possibility of a nucleus reacting not with an additional monomeric molecule, but with a second nucleus. The velocity of chain-growth may be further increased and the formation of longer chains favoured by reactions of this kind. That they actually occur may be seen from the kinetics of the condensation reactions

<sup>15</sup> See, for instance, K. F. Bonhoeffer, *Ergeb. exakt. Naturw.*, 1927, 204; Bonhoeffer and Hartack, *Grundlagen der Photochemie*, Steinkopf, Leipzig, 1933, p. 210, where further references are given.

of polybasic acids with polyvalent alcohols. Were it not for the occurrence of reactions of the last-mentioned kind, we could hardly expect the velocity of chain-growth to exceed the velocity of the formation of nuclei in this case too. The whole kinetics of the polymerisation must be therefore different from that discussed above. Experiments show, however, that this is not the case; indeed, condensation reactions of this kind lead to a similar distribution of chain lengths as the ordinary polymerisations.

(b) We may further consider the possibility of *isomerisation* or *saturation* of the unsaturated nuclei, by which they lose their capacity of further growth. The doubly unsaturated radical formed by two monomeric styrene molecules can, for instance, be converted into a saturated molecule in one of the following two ways:—

Analogous possibilities exist for longer chains also, so that the breaking of reaction chains by intramolecular isomerisation or by ring-formation must be taken into account in a full discussion of the kinetics of polymerisation. As shown by the above formulae, the isomerisation occurs by a hydrogen atom wandering along the chain. It is finally fixed on one end of the chain, a double-bond being formed simultaneously on the opposite end. From this mechanism we may reasonably expect the velocity of isomerisation to become smaller with growing chain-length. In this way, a relatively high number of short chains are stabilised and the proportion of short chains in the ultimate product of polymerisation increased.<sup>16</sup> In analogy to what we know about intramolecular transformations in general, we may expect the dependence of the isomerisation velocity on temperature to be relatively small. In any case, its activation-energy will be much smaller than that connected with the formation of nuclei.

We have included the influence of the isomerisation upon the kinetics of the polymerisation into the following formulae, under certain plausible assumptions, and for the case of a bimolecular formation of nuclei.

(c) We must not completely neglect the possibility of newly-formed long-chain molecules dissociating again, especially if the temperature of polymerisation is somewhat high and the chains already long enough. As already pointed out by Staudinger, and confirmed by many recent investigations, the large molecules are not comparable in stability with the small ones; they must therefore dissociate at relatively low temperatures. Still, we may reasonably doubt whether any perceptible dissociation really occurs at temperatures between 100° and 200° C.; but only special experiments could definitely answer this question. In the meantime, it appears necessary to include this effect into the general theory of polymerisation. Very conveniently, there exists a detailed investigation by W. Kuhn<sup>17</sup> of the dissociation of long chains,

<sup>16</sup> An analogous reasoning can also be used in the case of ring-formation. In connection with this problem we are developing a detailed theory of the kinetics of ring-formation from the point of view of intramolecular statistics.

<sup>17</sup> W. Kuhn, *Ber.*, 1930, 63, 1503.

made as a part of an extensive work undertaken by him together with K. Freudenberg and concerned with the hydrolysis of the cellulose.<sup>18</sup> In this paper by Kuhn, formulae are given for the dissociation-velocity of long chains under different conditions. Part of them can be directly applied to the thermal de-polymerisation of chain-molecules, whereas another part requires only small adjustments to be used to this purpose. The formation and dissociation of chains lead to an equilibrium dependent on temperature and on the molecular properties of the substance in question. The equilibrium constant can be represented in terms of the collision factors and the activation energies of both reactions.

(d) Another important complication, which may have a great influence on the properties of the products of the polymerisation, occurs when the nuclei still contain double bonds. This is the case with a great number of polymerising substances, as, for instance, with butadiene, isoprene, dimethyl-butadiene and chloroprene—as well as with those compounds which are known as “synthetic rubbers,” in consideration of their elastic properties. The experiments show, that nuclei of this kind may have their double bonds reduced to single bonds by appropriate activation, thermal or catalytic; the valencies which are set free in this way are used for linking the chains together, the result being the formation of a two- or three-dimensional lattice.\* The products which are thus obtained have properties entirely different from those of the ordinary chain polymers, especially in regard to solubility, melting-point and elasticity. We must therefore introduce into our equations a *velocity of space filling*, in addition to the velocity of chain-growth, in order to take into account a side-reaction which may become so important under suitable conditions. The results obtained by Carothers and collaborators in the study of chloroprene show that a thermal space filling is a process highly dependent on catalysts. Since it involves an activation of the double bond, we may expect the same catalysts to be active in this case as we found to accelerate the formation of polymerisation-nuclei. This conclusion is, so far, confirmed by experiment. In the absence of catalysts,<sup>19</sup> the activation energy of space filling may be supposed to amount to about 30-50 k. cal. per mol—i.e. equal to that of the formation of the nuclei. It appears, furthermore, plausible to suppose the probability of a chain taking part in a space filling to be proportional to the number of double bonds present in it. In the case of the above-mentioned substances, this means a proportionality to the chain-length. The velocity of space filling must therefore grow very quickly (exponentially) with increasing temperature, and gradually (linearly) with increasing chain-length. Both these conclusions accord with experiment. The inclusion of the space filling reactions into the mathematical scheme of the polymerisation process seems to offer no insuperable difficulties. We have started calculations of this kind and will communicate them as soon as they are completed.

<sup>18</sup> Compare especially K. Freudenberg, *Tannin, Cellulose, Lignin*, Springer, 1933, p. 97.

\* We shall hereafter refer to this as “space filling.”

<sup>19</sup> Stress must be laid again on the fact, that it is extremely difficult to exclude practically the smallest traces of catalytically active substances. This is of practical bearing for instance in the technical production of different polymers of chloroprene ( $\alpha$ ,  $\beta$ ,  $\mu$ ,  $\omega$ —polymers).

## 2. Discussion of the Kinetics of Polymerisation.

It is not difficult to derive approximate formulae for the velocity of the reactions discussed qualitatively in the previous section. According to what has been said above, we have to consider separately the cases of a bimolecular and of a monomolecular formation of the nuclei.

We will denote by  $\mathbf{H}$  the molecules of the non-activated monomeric substance, and by  $\mathbf{H}_j$  those of the polymeric radicals built up from  $j$  simple molecules. All  $\mathbf{H}_j$  we consider, as described in the previous section, to be non-saturated, and able to grow further by addition of more molecules of  $\mathbf{H}$ .

The *monomolecular* mechanism by which an active nucleus is produced, can be described by the formula

where  $x$  denotes the energy which is necessary for the production of the nucleus. As mentioned above, this energy is usually somewhat high.  $\mathbf{H}_1$  denotes the newly-formed polymerisation-nucleus. Its further development can be described by the following set of formulae :

All the reactions (2) require only a small activation-energy and therefore proceed much more quickly than reaction (1). For the sake of simplicity we will assume that the velocity constant of all the reactions (2) is the same. The velocity constant of reaction (1) is smaller by 3 to 6 orders of magnitude.

The *bimolecular* formation of nuclei is described by the formula

The first polymerisation-nucleus is in this case the dimeric radical  $\mathbf{H}_2$ . Its growth is again represented by (2), under omission of the first equation :

In both cases, we have to supplement (1) and (2) by a formula representing the slow stabilisation of the radicals  $\mathbf{H}_j$  and the formation of stable chain-molecules  $\mathbf{S}_j$  :—

The stabilisation may also occur by collision with a foreign molecule  $\mathbf{B}$  :—

Since  $\mathbf{S}_j$  is supposed to be incapable of growing any further, reaction (3) and (3a) inhibit the polymerisation. The substances  $\mathbf{B}$  thus act as *negative catalysts*.

We neglected in this scheme reactions of the type of

which we discussed in the previous section. We did not do this because we supposed them not to occur at all or to be improbable from the kinetic point of view, but only because we found that their occurrence

does not appreciably change the general course of the polymerisation-process. This is suggested by the results discussed below.

The reactions (1), (2), (3) or (1), (2) and (3a) together form a typical reaction chain. All that is known about polymerisation agrees with the supposition that they are chain reactions. The chain structure of the polymers itself points in this direction.

The assumption of reaction chains is further supported by the occurrence of positive and negative catalysis. Negative catalysis is easily explained by reaction (3a), whereas positive catalysis is to be explained by a catalytic acceleration of reaction (1). The almost explosive manner in which many polymerisations take place is characteristic of chain reactions. The polymerisation of styrene and of acrylic ester is, for instance, accompanied by an intense foaming. A finer detail which fits well into the picture is the existence of an induction period (mentioned above). Calculations based on formulae (1-3) in fact lead to the prediction of an induction-time.

We shall denote the quantity of the initial substance **H** present at a given moment by  $M$ , the amounts of the radicals **H**, either by  $M_{j-1}$  (in the "monomolecular" case), or by  $M_j$  (in the bimolecular case). The initial concentration of **H** (at  $t=0$ ) we put equal to 1. By an appropriate choice of units, the reaction-constant of process (2) can also be made equal to 1. The velocity-constant of reaction (1), which we denote by  $a$ , is in this case equal to something between  $10^{-3}$  and  $10^{-6}$ . Irrespective of the units chosen,  $a$  has the meaning of the relation between the velocity-constants of (1) and (2). The stabilisation reactions (3) and (3a) will be disregarded for the moment.

#### (a) The Nuclei are Formed Monomolecularly.

The differential equations for (1) and (2) occurring together are in this case—the amount of **H**, being denoted by  $M_{j-1}$ —as follows:—

$$\begin{aligned}\frac{dM_2}{dt} &= aM - MM_2 \\ \frac{dM_3}{dt} &= MM_2 - MM_3 \\ \frac{dM_4}{dt} &= MM_3 - MM_4 \\ &\vdots \\ \frac{dM_n}{dt} &= MM_{n-1} - MM_n\end{aligned}\quad \dots \quad (4)$$

Putting  $Mdt = dz$  (5)

we obtain:—

$$\begin{aligned}\frac{dM_2}{dz} &= a - M_2 \\ \frac{dM_3}{dz} &= M_2 - M \\ \frac{dM_4}{dz} &= M_3 - M_4 \\ &\vdots \\ \frac{dM_n}{dz} &= M_{n-1} - M_n\end{aligned}\quad \dots \quad (6)$$

The transformation (5), leading from (4) to (6), means the introduction of a new time-factor  $z$ , which becomes greater with progressing reaction. We shall call  $z$  the *individual time* (Eigenzeit) of the reaction. For  $t = 0$ , also, we put  $z = 0$  too. The solution of the equations (6), with appropriate initial conditions, is

FIG. 1.

$$M_n = ae^{-z} \sum_{p=n-1}^{\infty} \frac{z^p}{p!} \quad (7)$$

Obviously,  $M_2 > M_3 > M_4 > \dots$ . With increasing  $z$ , the right side of (7) becomes less and less different from the expression:

$$ag(n, z) = \begin{cases} a & n-1 \leq z \\ 0 & n-1 > z \end{cases} \quad (8)$$

Using (8) instead of (7), we imply that the chains grow with a uniform velocity (referred to the time-scale  $z$ )—a result which appears immediately plausible. The discontinuity expressed by (8) is practically smoothed over by statistical scattering—that is why the correct formula is (7) and not (8).

For the amount of the non-polymerised substance  $M$ , we obtain:

$$M = 1 - az - \frac{az^2}{2} \quad (9)$$

The solution  $z = z_{\infty}$  of the equation represents the value of the individual time  $z$  after which the initial substance is completely used up. To the first approximation,  $z_{\infty}$  is given by  $\sqrt{\frac{2}{a}}$ . The individual time  $z_{\infty}$ , of course, corresponds to  $t = \infty$  on the ordinary time-scale. Introducing (9) into (5), we obtain

FIG. 2a.

$$\frac{dz}{dt} = 1 - az - \frac{az^2}{2} \quad (10)$$

as the relation between the individual ( $z$ ) and the ordinary ( $t$ ) time. The values of  $M_n$  which we obtain from (7) in putting  $z = z_{\infty}$  represent the

final quantities of the different polymers. The chain length which is present to the highest amount in the mixture is approximately equal

to  $0.9z_{\infty} = 0.9\sqrt{\frac{2}{a}}$ . (With (8) it would be  $z_{\infty}$  exactly).

FIG. 3.

Fig. 1 shows the distribution of chain-lengths to a time  $z = 10$ , corresponding to an early stage of polymerisation. Figs. 2 and 2a show the amount of polymerised substance  $S$ , as a function of the time  $t$ .

FIG. 3a.

Figs. 3 and 3a represent the final distributions of the chain-lengths, at  $t = \infty$ .

The formulae given so far are exact. The following are only approximate.

**(b) The Nuclei are Formed Bimolecularly.**

The differential equations corresponding to (1) are now :—

$$\begin{aligned}\frac{dM_2}{dt} &= aM^2 - MM_2 \\ \frac{dM_3}{dt} &= MM_2 - MM_3 \\ &\dots \dots \dots \\ \frac{dM_n}{dt} &= MM_{n-1} - MM_n \\ &\dots \dots \dots\end{aligned}\quad (11)$$

In introducing again the individual time  $z$ , when using relation (5) instead of the ordinary time  $t$ , we obtain :—

$$\begin{aligned}\frac{dM_2}{dz} &= aM - M_2 \\ \frac{dM_3}{dz} &= M_2 - M_3 \\ &\dots \dots \dots \\ \frac{dM_n}{dz} &= M_{n-1} - M_n\end{aligned}\quad (12)$$

FIG. 4.

The solutions of (9) are :—

$$M_n = ae^{-z} \sum_{p=n-1}^{\infty} \frac{z^p}{p!} - \begin{cases} \frac{a^2}{2}(z-n)^2 & \dots n < z \\ 0 & \dots n > z \end{cases} \quad (13)$$

and

$$M = 1 - 2az - \frac{az^2}{2} + \frac{a^2z^4}{24} \quad (14)$$

The value  $z_{\infty}$  which corresponds to a given  $a$  is now greater by about  $\frac{1}{8}$ , viz.  $\frac{9}{8}\sqrt{\frac{2}{a}}$ . Figs. 4 and 4a are examples of the final distributions of the

chain-lengths. Figs. 2 and 2*a*, representing polymerisation as a function of time, remain valid in this case too. The existence of an induction period is clearly shown by these graphs. The most favoured chain-

length is again equal to about  $0.9 z_{\infty}$ —which now means  $0.9 \times \frac{9}{8} \sqrt{\frac{2}{a}}$ .

### (c) The Influence of the Stabilisation Reaction (3).

We supplement now the above discussed scheme by the reaction (3), with a velocity-constant  $b$  of its own, supposed to be independent of  $j$ . What is the final distribution  $\mathcal{F}_j(z_{\infty})$  of the  $S_j$ -values at  $z = z_{\infty}$  (or  $t = \infty$ ). If  $b$  is so small that reaction (3) intervenes only when the polymerisation is practically completed, then the distribution curve must practically coincide with the former curve  $M_n(z_{\infty})$ . In all other cases, the number of shorter chains is increased and that of the longer chains diminished by the intervention of reaction (3).

FIG. 4a.

FIG. 5.

On the assumption of a bimolecular formation of nuclei we obtain:—

$$\mathcal{F}_n(z_{\infty}) = \left( \frac{2z_{\infty} - n}{2z_{\infty}} \right)^{\frac{\pi b}{4\sqrt{a}}} M_n(z_{\infty}) + \begin{cases} (\pi b \sqrt{a} \cos \sqrt{a} n \dots n < z \\ 0 \dots n > z \end{cases} \quad (15)$$

This formula holds, however, only if  $\frac{\pi b}{4\sqrt{a}}$  is much smaller than 1. Because  $n > 1$  the factor which stands before  $M_n$  is smaller than 1 and the first term therefore smaller than  $M_n$ ; the second term increases the relative probability of the short chains.

Negative catalysis of the type (3*a*) fits into the same scheme so long as the concentration of the catalyst does not decrease appreciably in the course of the polymerisation—i.e. so long as the stabilisation (3*a*) obeys formally a monomolecular law.

### 3. Comparison of the Theory with the Experimental Results.

On comparing the experimental curves 5 and 5*a*, which describe the polymerisation of styrene as a function of time, with the "theoretical" curves in Figs. 2 and 2*a*, we observe a general agreement in their shape:

an induction-period is followed by a linear section of the curve, which finally becomes concave and approaches the horizontal when the polymerisation is nearing completion. We may therefore say that the theory describes the process of polymerisation in an essentially correct way.

FIG. 5a.

A more detailed analysis reveals that whereas theory predicts a relatively long induction period (lasting until about 10-15 per cent. of the substance is transformed), the experimental induction times are apparently much shorter. In many cases, for instance, in those of indene and of dimethyl butadiene (Figs. 6, 7 and 8), there appears to be no induction period at all.

FIG. 6.

FIG. 7.

In order to show how far the theoretical equations are capable of representing the experimental results, we plotted together, in Fig. 9, the theoretical curve for  $a = 10^{-3}$ , and the experimental results obtained with styrene at 80°.

We must remember here, that measurements in the liquid phase are not very appropriate for comparison with the theory. The single chain growth reactions are exothermic; the temperature shown by a thermometer immersed in the reacting liquid is therefore not identical with that

prevailing in the immediate neighbourhood of the reacting molecule. We must suppose, on the contrary, that the temperature of the polymerising substance

FIG. 8.

itself is often much higher than the mean temperature of the liquid, thus permitting a much higher velocity of formation of the nuclei and making the induction period shorter. Moreover, we must remember that small amounts of catalytically active substances may increase the initial velocity of the formation of nuclei and thus also reduce the induction period. Measurements of the polymerisation velocity in solutions can be expected to give results more appropriate for comparison with the theoretical curves. Unhappily, these measurements are not yet carried so far as to enable their results to be used in this discussion.

FIG. 9.

### Summary.

(1) The kinetics of polymerisation processes are discussed from the point of view of a slow nucleus-forming reaction, followed by a quick growth of the chains.

(2) The following side-reactions are discussed :—

- (a) Isomerisation.
- (b) Dissociation of chains.
- (c) Intercombination of nuclei.
- (d) Formation of lattice.

(3) The influence of catalysts on both stages of the main reaction is considered.

(4) Formulae are derived for the above polymerisation-mechanism, both for a monomolecular and for a bimolecular formation of nuclei.

(5) The influence of isomerisation is introduced into the formulae.

(6) The theoretical results are compared with the experiments, so far as this appears possible to-day. The comparison reveals that the simple theoretical mechanism corresponds qualitatively to the experimental picture, and is even able to reproduce the experiments with styrene quantitatively with a high degree of accuracy. In discussing the finer details of the polymerisation-processes, however, the side-reactions mentioned under (3) must undoubtedly be taken into consideration too.

Wien: 1. Chemisches Universitäts-Laboratorium.

### GENERAL DISCUSSION

Dr. Albert Wassermann (London) said: In studying bimolecular reactions of the type  $a + b \rightarrow c$ , it is sometimes observed that the constant  $Z$  of the Arrhenius equation  $k = Ze^{-E/RT}$  decreases rapidly as the number of atoms of which the molecules  $a$  and  $b$  consist is increased.<sup>20</sup> The figures given below represent a good example:—

KINETICS OF DIENE SYNTHESSES (ADDITION OF QUINONES TO *cyclopentadiene*); BENZENE SOLUTION.

No.	(a).	(b).	(c).	$Z$ <sup>21</sup> .	$E$ <sup>21</sup> .
1	$C_6H_4O_2$	$C_5H_6$	<i>cyclopentadiene</i> Benzoquinone	$1 \times 10^6$	11.6
2	$C_{10}H_8O_2$	$C_8H_8$	<i>cyclopentadiene</i> $\alpha$ -Naphthquinone	$7 \times 10^4$	10
3	$C_{11}H_{10}O_2$	$C_8H_8$	Di- <i>cyclopentadiene</i> Benzoquinone	$3 \times 10^4$	13

The  $Z$  value of the reaction ethylene + ethylene ( $a = b = C_2H_4$ ) amounts, according to Pease,<sup>22</sup> to  $2 \times 10^6$ . It can be seen that the  $Z$  values of the diene syntheses (reacting molecules containing 12–23 atoms) are much smaller. The difference is so large that it might be wondered how the formation of highly polymerised compounds occurs at all. The possibility of the synthesis of these compounds must evidently depend not only on a very low activation energy.<sup>23</sup> The "temperature independent factor"  $Z$  of the Arrhenius equation must also be increased in some "abnormal" manner under certain experimental conditions.

Dr. J. H. de Boer (*Eindhoven*) said: The mechanism of growth of the nuclei and the chains by an addition process of monomeric molecules on the top of the chains with a high velocity brings to mind the process of crystal growth, e.g., of mercury crystals in the classical experiment of Volmer and Estermann. Now, in these latter cases the velocity of growth is large because a large number of the atoms or molecules striking the sides of the growing needle-crystal are loosely bound there by adsorption forces

<sup>20</sup> Cf. Evans and Polanyi, *Trans. Faraday Soc.*, 1935, **31**, 875; Eyring, *J. Chem. Physics*, 1935, **3**, 107. Cf. also Rice and Gershinowitz, *ibid.*, 1934, **2**, 853.

<sup>21</sup> The dimension of  $Z$  is 1/g.-mol.-sec. and that of  $E$  is Cal.

<sup>22</sup> *J. A. C. S.*, 1932, **54**, 1876.

<sup>23</sup> It should be borne in mind that the activation energy of the association of two triphenylmethyl molecules is 8 Cal.

and migrate to the top, where they contribute to the lengthwise growth. Is such a mechanism possible, also, in the case of the growing polymers?

**Dr. D. Finlayson** (*Long Eaton*) said: Reference has been made to the fact that the rate of growth of long-chain compounds is greater than would be expected from the standpoint of the conventional theories. The explanation of this must be looked for on lines other than those so far considered, and in this connection, I would suggest that Dr. Carothers' remarks about the analogies between vital growth and the process of polymerisation are worthy of the closest study.

In both processes, long-chain molecular complexes, in suitable environments which contain molecules fundamentally of the same nature as those forming the units in the molecular chains, are able to grow by a series of chemical interactions between the end of the chain and the appropriate molecules of the environment. These processes differ from ordinary crystallisation mainly in that the mechanism by which the correct molecules are selected from the environment, and suitably oriented with respect to the molecules at the end of the chain, would appear to be rather more complicated. I suggest that the mechanism of selection and orientation is as follows.

Any molecular chain is necessarily in a state of active vibration before growth can occur. The energy to initiate and maintain the necessary intensity of vibration may be derived either from thermal collisions with the material of the environment or from an external source of radiant energy. The vibrations thus acquired by the molecular chain will be received in a series of impulses which may, or may not, have some connection with the natural vibration period of the unit of the molecular chain. In either case, these impulses will travel as series of waves backwards and forwards along the molecular chain, and the resulting motion may be regarded as the superposition of a random motion on the fundamental and harmonic vibrations of the molecular units of the chain. For our purpose, the random motion may be neglected; the important point is that a series of random impulses is able to stimulate a chain to vibrate with its own natural vibrations (on which are superposed other random oscillations).

When these natural vibrations reach a free end of the molecular chain, they must (as in sound waves at the open end of a pipe) partly return along the chain with diminished intensity, and partly tend to dissipate themselves in the surrounding medium. In other words, a long-chain molecular complex tends to produce, continuously, in the medium at the end of the chain a vibration "like" that of the unit of the chain itself. The effect of this will be to orientate the molecules of the medium at the end of the chain in such a way as to make it possible for the vibration to be transmitted, *i.e.*, the molecules of the medium will present themselves to the end of the chain in the configuration of the units of the chain themselves. It is thus that, I imagine, growth will occur.

It has been remarked that any rational explanation of polymerisation must also explain depolymerisation. It may be suggested that the mechanisms of both processes are, essentially, the same.

When a long-chain compound is "deprived of its food," or placed in an environment which does not contain any "like" molecules capable of dissipating its characteristic vibrations, the amplitude of these vibrations must, in general, increase. The result will be that, from time to time, certain molecular chains will acquire amplitudes of vibration greater than they are able to withstand, and these chains will be torn asunder, the most probable positions of rupture being near the centre of each chain. Thus, in simple long-chain compounds, as in complex living organisms, the absence of opportunity for growth, in time, results in death.

**Dr. R. Spence** (*Leeds*) said: Some three years ago, I studied the polymerisation of gaseous formaldehyde in pyrex vessels at room temperature.<sup>24</sup> The pressure decreased at first unimolecularly, then bimolecularly, and

<sup>24</sup> Spence, *J. Chem. Soc.*, 1933, 1193.

finally the rate slowed down according to a higher order. The nature of the polymeric deposit is of some interest in connection with Dr. de Boer's suggestion that there might be a surface diffusion to the centres of growth. Most of the glass surface appeared to be covered with a thin translucent film of varying thickness, in addition to which small nodules could be observed, sometimes reaching 2 mm. in diameter. Furthermore, the velocity of polymerisation was closely proportional to the area of surface present, and it might be supposed that the rate depended upon the degree of adsorption of the formaldehyde upon the polymer and the diffusion of the adsorbed molecules to the active centres. The kinetic data, on the other hand, do not support this view, but indicate rather that the rate depends upon the number of active centres present. It is of interest to note that growth appears to continue on the same regions of the deposit in consecutive experiments in spite of evacuation and the lapse of time between them.<sup>25</sup> Accordingly, two kinds of activity may be involved, namely that associated with the growing chain, and a more permanent type capable of initiating new growth.

**Dr. E. Heymann (London)** said: Professor Mark asks how one could determine the distribution of molecular weights in a solution of polymers which contains molecules of different molecular weight (or chain-length).

Let us assume we have three different groups of molecules of different chain-length (or molecular weight), and let us furthermore assume, that these molecules are dipoles. If these are exposed to an alternating electric field, there are characteristic frequencies  $\gamma$  for each group of molecules, at which they become oriented in the field. The critical frequency (wave-length  $\lambda$ ) will be the smaller ( $\lambda$  higher), the larger the molecules (Debye).<sup>26</sup> If, therefore, we measure the dielectric constant  $\epsilon$ , in relation to the wave-length, we find for small wave-lengths the dielectric constant of the pure solvent ( $\epsilon_0$ ). If we increase the wave-length to a certain value, the smallest molecules will be oriented in the field, and thus contribute to the orientation polarisation, that is to say, we observe a rise in dielectric constant ( $\epsilon_1$ ). If we increase the wave-length further, we shall come to a region where the molecules of larger size become oriented, and consequently, we shall observe a second rise in dielectric constant ( $\epsilon_2$ ). With further increase in wave-length the largest molecules will contribute to the orientation polarisation and the dielectric constant will rise again ( $\epsilon_3$ ) (Fig. 10). That is to say, for every group of molecules there corresponds a dispersion region in the  $\epsilon$ - $\gamma$  curve. In practice, the conditions will often be more difficult, since the mixture need not necessarily contain distinct groups of molecular weights. If the molecular weights are very close together, it will not be possible to distinguish between the single dispersion regions, which in this case will grow together to one very broad region, in which the dielectric constant increases slowly with increasing wave-length.

It is true that dielectric constant measurement with variation of wave-length involves experimental difficulties, especially if small wave-lengths are required. Molecules of colloidal dimensions correspond to wave-lengths between about 5 and several 100 metres. Other complications may arise, if the dipole is not fixed in the molecule or if a part of the molecule is oriented independently or almost independently (as suggested by Professor K. H. Meyer). In any case, I think that it is worth trying the dielectric-constant method for getting information about the distribution of molecular sizes in solutions of highly polymerised substances, especially as a similar method has been suggested by N. Marinenco,<sup>27</sup> and by J. Errera and his co-workers<sup>28</sup> to determine the molecular weights of proteins in solution.

Dr. E. A. Moelwyn-Hughes (*Cambridge*) said: If, in the present reaction, the disparity between the behaviour in the gas phase and in solution can be adduced as evidence for the mechanism outlined by Professor Rideal and Professor Mark, then the results of Abkin and Medvedev (p. 286) would appear to indicate quite a different mechanism for the sodium-catalysed polymerisation of butadiene.

Professor H. Mark (*Wien*), in reply, said: To save time I will discuss together the most interesting results of Dr. Wassermann and the very striking remark of Dr. de Boer. In both cases the question is how does the rate of chain growth depend upon the length of the chain? a point which seems to me to be fundamental in the kinetics of polymerisation reactions. In our contribution Dr. Dostal and I made our first calculations on the assumption that the growth constant of a growing chain would be independent of its actual length. This procedure, which must be, of course, taken as a first approximation, seemed to be justified to a certain extent by the fact that one generally can assume that, with increasing chain-length, the heat of activation and the steric factor for the next elementary addition process both decrease. It can happen, as Professor Rideal has

FIG. 10.

already pointed out, that these two influences more or less compensate one another. This may be the case, but it does not necessarily follow. It was therefore necessary to improve the calculation as to the building up of long chains, and to work out a formula, which includes a certain variability of the chain growth constant. Dr. Dostal was able to show that one can accomplish the calculation also for the fact that  $K_n$  is not constant, but depends upon  $n$ . For the dependence of the reaction constant upon the chain-length, one has put  $K_n = A \cdot \alpha^n$  where  $n$  is the number of the members of the chain and  $A$  and  $\alpha$  are constants.

This equation allows the assumption of an increasing or decreasing probability for the next step with growing chain-length.<sup>29</sup>

It is probable that, in most cases, the rate of growth will decrease with increasing chain-length because the energy of activation of the growing reaction is already so small, when the chains are short, that its decrease during the growth cannot very much affect the velocity of the reaction. On the other hand, there are very good reasons to assume that the steric factor will decrease very rapidly, when the size of the reacting molecules

<sup>29</sup> See also Dr. Dostal's remarks concerning Dr. Bawn's paper, p. 183.

increases. All our knowledge of the kinetics of bimolecular reactions in the gaseous state (and particularly also in dilute solutions), the experiments mentioned by Dr. Wassermann, and last but not least, the theoretical considerations of Eyring, Evans and Polanyi, and the recent work of Hellmann and Syrkin, show that the steric factor of a bimolecular reaction may decrease to  $10^{-2}$ , when the reacting molecules have a considerable size. The reason for this behaviour is (as Dr. Bawn will point out in his paper) not so much geometrical considerations, as the fact that we have an interaction of oscillating systems, which obey the laws of quantum mechanics and have to fulfil different conditions, if a mutual reaction is to be allowed. One should therefore assume that, generally, the chain-growth constant should decrease very rapidly with increasing chain-length; this leads to the result that long chains could not be built at all. Experiment shows very clearly, on the contrary, that they are formed in nearly every case when polymerisation takes place at all.

In connection to the contribution of Dr. de Boer, I would add that it seems quite possible that some kind of adsorption of the monomeric molecule on the surface of the polymeric macromolecule plays a similar rôle, as it does in the case of crystal growth. Therefore the analogy, which Dr. de Boer has pointed out seems to me to be very reasonable, and the idea of Volmer, which was so useful in the case of crystal growth, may be of the same use in the growth of long chain molecules. In fact, similar processes have already been taken into account. Dr. Medvedev refers to this in his contribution, where he meets a similar difficulty from an "activation" of the monomeric through the polymeric macromolecule.

To what extent such an activation may be due to surface processes, as Dr. de Boer suggested, will only be cleared up by very careful quantitative analysis of polymerisation reactions: this is not at all easy, and must be worked out with the greatest care for every single polymerisation substance.

In reply to a remark by Dr. Kienle, I would like to point out, that in the case of the esterification of polyvalent alcohols with polybasic acids and in the case of the mutual esterification of  $\omega$ -oxycarbonic acids the reactions which respectively start the chain and propagate the chain are essentially of the same type. It therefore seems probable that they have reaction rates of the same order of magnitude. Of course, one has to take in account, that the growth reaction will decrease in rapidity with increasing chain-length, while the "starting" reaction will be independent of the extent of condensation. In any case, there is no reason for a very rapid growth-reaction, so that it may be better to speak not of a chain-reaction but of a step-reaction. In such a type of reaction one does not get so long chains as in the case of very rapid growth, and one has to expect always to find a somewhat large amount of intermediate products, i.e., chains of medium length, as Dr. Kienle has pointed out. This seems also to account for the fact, which especially Staudinger mentions, that one gets chain-like condensation products mostly only in the hemicolloid state, and does not reach really high polymeric specimens. The rate of building up nuclei is here of the same order of magnitude as the velocity of growth, and the large number of nuclei formed per unit of volume and time is always competing with the growing chains, with the result that very long molecules cannot be built.

# THE KINETICS OF LONG CHAIN DISINTEGRATION APPLIED TO CELLULOSE AND STARCH.

BY PROFESSOR KARL FREUDENBERG (*Heidelberg*).

*Received 7th August, 1935.*

In 1921 evidence was given in favour of the concept that cellulose is a long chain molecule of *equally* linked glucose residues.<sup>1</sup> The reasoning was based on the kinetics of long chain disintegration. The maximum yield of cellobiose, from such a system, would exceed 30 per cent. but would never reach 100 per cent.; under certain circumstances it would approach 67 per cent. This was confirmed by experiment.

It was later found that cellulose when hydrolysed with 50 per cent. sulphuric acid at 18° has a lower velocity of reaction than cellobiose ( $K_n = 0.36 \times 10^{-4}$ ,  $K_2 = 1.07 \times 10^{-4}$ ,  $K_n$  being the velocity in the first stage of cellulose hydrolysis,  $K_2$  the constant of cellobiose).<sup>2</sup> Werner Kuhn carried out the calculation of the process<sup>3</sup> on the assumption that the velocities  $K_3$ ,  $K_4$ , etc., with which cellotriose, cellotetraose, etc., are attacked at the incipient hydrolysis, lies between  $K_2$  and  $K_n$ . The calculations are in good agreement with the experimental curve. Werner Kuhn's formulæ are also the basis for the calculation of disintegration processes of all other long chain molecules.

The experiments mentioned were based on the iodometric estimation of the aldehyde group. When the optical rotatory power is observed during hydrolysis, similar curves are obtained, which could also be calculated by additive formulæ: also given by Werner Kuhn.

In connection with these experiments it was found that the molecular optical rotation of biose, triose, tetraose, etc., is additive and leads to the rotation of the polysaccharide by a linear function.<sup>4</sup> This fact has been explained by optical superposition and has been confirmed for cellulose and starch and their methyl derivatives. It has been, so far, the strongest evidence for the fact, that in cello-biose, -triose, and -tetraose, as well as in cellulose itself, only *one* kind of linkage occurs, which is uniform in structural and configurational aspect. Methyl-starch and its methylated oligosaccharides behave in the same manner.

The uniformity of the cellulose bond has now been confirmed by G. Blomqvist. He determined the velocity of hydrolysis of L. Zeche-meister's cellotriose and cellotetraose.  $K_3$  and  $K_4$  (incipient velocity at 18° C.) are  $0.636 \times 10^{-4}$  and  $0.506 \times 10^{-4}$  respectively. The former experiments have been repeated and completed, the figures being now:

$K_2$ . .	$1.07 \times 10^{-4}$	$6.94 \times 10^{-4}$	$1.43 \times 10^{-4}$	$10.3 \times 10^{-4}$
$K_3$ . .	0.636 "	4.50 "	—	—
$K_4$ . .	0.506 "	3.65 "	—	—
$K_n$ . .	0.305 "	2.34 "	0.97 "	7.0 "

From these figures the heat of activation  $U$  and the steric factor  $A$  may be approximately calculated.

	Cellobiose.	Cellotriose.	Cellotetraose.	Cellulose.	Maltose.	Starch.
$U$ . . . .	27.300	28.600	28.900	29.800	28.800	28.900
$A \times 10^{-16}$ .	3.4	18	24	67	64	52

The velocities of hydrolysis of cellotriose and -tetraose lie between those of cellobiose and cellulose, indicating once more that a continuous sequence leads from biose over the oligosaccharides to the polysaccharide. The crystalline cellodextrine of M. Bergmann and of K. Hess, formerly called bioseanhydride or biosane, fits into this series. Its degree of polymerisation may be assumed to be about 30.

The assumption made by Werner Kuhn for the calculation of the hydrolysis of polysaccharides has therefore been confirmed by experiment.<sup>5</sup>

The figures obtained with the two main constituents of potato starch indicate that amylo-amylose possessed a lower average degree of polymerisation than amylo-pectin. Both preparations are mixtures of polymer homologues, representing fairly long chains. The optical behaviour is in agreement with this conclusion.

### GENERAL DISCUSSION

**Professor H. Mark** (*Wien*) said: Table II. contains a result which is of interest in connection with our general knowledge of high polymeric substances. One assumes generally (and, so far as one can see, also in agreement with experiment) that long chain molecules dissociate more readily with increasing chain-length. In contradiction to this, the measurements of Freudenberg show that the activation energy of the hydrolysis of cellulose is distinctly greater than that of cellobiose, cellotriose and cellotetraose. This may be due to the fact, that the hydrolysis of cellulose does not take place in a really homogeneous medium, but that one has a degradation in the swollen state. It may be that the glucosidic oxygen-link is strengthened by its position in the lattice; this would mean, that during the growth process of cellulose a certain gain of energy takes place.

**Dr. E. A. Moelwyn-Hughes** (*Cambridge*) said: The critical increment for the hydrolysis of cellobiose (27,300 calories) is the only one which deviates markedly from the mean critical increment (29,000) for the remaining reactions to which the data in Professor Freudenberg's second table refer.

<sup>5</sup> A. af Ekenstam (*Svensk Kem. Tidskr.*, 1934, 46, 157) states that in 65 per cent. sulphuric acid solution cellulose hydrolyses on the lines of a monomolecular process. By repeating his experiment we were unable to confirm his results. His assumption that 50 per cent. sulphuric acid is not an adequate medium can likewise not be accepted.

Combining his figures for the velocity of hydrolysis of this disaccharide at temperatures of 18° and 30° C. with my values,<sup>6</sup> at 60° and 80° C., I find the velocity constants over the complete temperature range to be satisfactorily given by an expression where  $E = 29,000$  calories. The two sets of experiments necessarily refer to systems containing different concentrations of catalyst, but independent experiments show that  $E$  is not sensitive to the concentration, so that the combination of the results is justified. The revised critical increment for the hydrolysis of cellobiose is thus in good agreement with the other values quoted in the paper, and strengthens Professor Freudenberg's argument. As Professor Haworth appreciated some years ago,<sup>7</sup> the critical increment is a much more reliable guide to the structural stability of carbohydrates than is the velocity itself. Further evidence in support of this view is to be found by comparing the hydrolysis of derivatives of the normal glucoses, including cellulose and starch, with the hydrolysis of derivatives of the "active" glucoses, or substituted glucofuranoses.  $E$  for the former class appears to be insensitive to temperature, whereas  $E$  for the latter class falls with a rise in temperature.<sup>8</sup>

If we express the velocity constant for a bimolecular reaction in the form  $k = P \cdot Z \cdot e^{-E/RT}$ , where  $E$  is the Arrhenius critical increment and  $Z$  is the gas-kinetic collision frequency, it is found that  $P$  sometimes varies from reaction to reaction. There seems now a fairly general agreement to accept, provisionally, the classification of bimolecular reactions into those having fast, normal or slow rates, according as  $P$  exceeds, equals or is less than one. In point of time, the slow reactions were first discovered.<sup>9</sup> The next set of reactions in solution to which kinetic considerations were applied were fast reactions.<sup>10</sup> Finally, research among some of the oldest publications extant revealed the existence of a number of reactions with normal velocities.<sup>11</sup> This chronological recapitulation has been deemed necessary because the existence of the fast reactions has been almost consistently ignored in the recent discussions of the factor  $P$ . The new experimental material supplied by Professor Freudenberg in the present paper should freshen our memory to the fact that  $P$  is known experimentally to vary from  $10^{-9}$  to  $10^9$ . These figures are not in any sense limiting values; they are simply the smallest and largest experimental magnitudes of which I am personally aware.

Professor K. Freudenberg (Heidelberg), in reply, wrote: It is true that the polypeptides of glycine are more readily hydrolysed with increasing chain-length. In the same way cellulose suffers acetolysis with acetic anhydride and sulphuric acid more readily than cellobiose. However, cold 50 per cent. sulphuric acid hydrolyses cellulose more slowly than cellobiose. It has been shown by experiment that cellobiose has a velocity constant lower than triose, and triose lower than tetraose. From this it follows that the behaviour of cellulose is not due to the way in which it is brought into solution, i.e., by heterogeneous conditions. I am convinced that the solution of cellulose is a true solution soon after dissolution, when the first titration is carried out, since the solution shows no viscosity.

The slower reaction of cellulose compared with that of the lower saccharides depends upon an increase of the activation energy, for the activation energy of the central groups is higher than that of the terminal groups. The phenomenon is based on the fact that the terminal groups are linked to the others by an affinity energetically different from that with which they are linked to central groups, whereas Professor Mark presumes equal energetic conditions for all linkages. This has already been discussed by W. Kuhn.<sup>12</sup>

# X-RAY SPECTROGRAPHY OF POLYMERS AND IN PARTICULAR THOSE HAVING A RUBBER-LIKE EXTENSIBILITY.

By J. R. KATZ.

*Received 13th August, 1935.*

## 1. Introduction.

For many years H. Staudinger defended the theory that polymers have—in the simplest case—a long chain form of molecules in which a certain small unit repeats itself regularly along the chain, the units being united by primary valencies. His arguments were not, however, at the beginning of 1927, sufficiently convincing. The decisive argument was forthcoming shortly afterwards by the application of X-ray spectrography. I would like to begin this article by bringing a few personal memories about this development.

At the meeting of the *Naturforscherversammlung* in Innsbruck in September, 1924, I first heard him defend this theory, especially for the case of polyoxy-methylenes, but also for some other cases. Neither I myself nor some others to whom I spoke were convinced by his very interesting exposition. His conception seemed possible, but, many of us thought, not proved. And the whole subject did not yet look attractive to many of us.

At the meeting of the *Naturforscherversammlung* in Düsseldorf in September, 1926, where a symposium on high molecular weight substances was held, he again defended this theory. In 1926, the interest in the subject had already increased a good deal, as is clearly shown by the fact that a symposium on the subject had been arranged. Yet, Staudinger's conceptions did not seem to many of us really convincing, nor was the decisive value which X-ray spectrography could have for the subject yet understood at this meeting.<sup>1</sup> Under these circumstances there can be little doubt that the priority of the idea of the long chain molecules for polymers is chiefly due to H. Staudinger.

At the time this symposium in Düsseldorf was held (Sept. 1926) X-ray spectrography had not yet given the decisive argument as to the form of the molecules it would give later; it presented on the contrary a new difficulty in understanding them. H. Mark presented this situation, as it seemed at that moment, very clearly in his lecture for the Düsseldorf symposium.<sup>2</sup> All the X-ray data collected between 1920 and 1926 showed that the elementary cells of the crystals of all the high molecular weight substances then investigated (cellulose, stretched rubber, silk fibroin, etc.) are small, their weight not exceeding 800 times that of a hydrogen atom. Yet much physico-chemical and chemical evidence points to the fact that these substances, including highly polymerised synthetic polymers, have on the contrary a very high molecular weight,

<sup>1</sup> H. Staudinger, *Berichte*, 1926, **59**, 3019, containing his lecture at Düsseldorf.

<sup>2</sup> See the lecture of H. Mark, *Berichte*, 1926, **59**, 2982.

ranging in the tens or hundreds of thousands. It was still doubtful at the Düsseldorf meeting how this fundamental contradiction could be explained.

Some of us who worked on the X-ray spectrography of high molecular weight substances had discussed as one of the possibilities, the assumption that the molecules might perhaps be very much longer than the elementary cell of the crystals. M. Polanyi (1921) and R. O. Herzog (1921)<sup>3</sup> early in the development of the X-ray spectrography of the high molecular weight substances discussed the possibility of such an assumption, without however deciding in its favour. I myself in 1924, in writing my first survey on X-ray spectrography of swelling, discussed the same hypothesis.<sup>4</sup> And in 1925, in describing the X-ray phenomena obtained in stretching rubber, I even made this same assumption as the probable explanation.<sup>5</sup> K. Weissenberg discussed the same possibility in 1925.<sup>6</sup> Yet none of us worked this idea out completely for one substance.

In June, 1926, however, a young Californian botanist, O. L. Sponsler, made this next step.<sup>7</sup> In the American Colloid Symposium, June, 1926, held at the Massachusetts Institute of Technology at Cambridge, Mass., he brought a complete picture of the cellulose molecule and how it lies in the elementary cell. He visualised the unit which repeats itself, the  $C_6H_{10}O_5$ , as a pyranose ring, the side chain  $-CH_2OH$  being turned alternately to the left and the right, the unit being joined by primary valencies (glucosidic bindings) to a chain form molecule. This molecule is *very much longer* than the elementary cell. He described, using Bragg's sphere models, how the carbon and oxygen atoms lie in the elementary cell.

This was the first full picture which showed how to combine the assumption of the long chain molecule with the small elementary cell found by the X-ray workers and as such has now become a classic (although later Kurt H. Meyer and H. Mark had to make some changes in Sponsler's picture for cellulose, because they seemed more probable.<sup>8</sup>)

Then, in 1927 G. Mie and J. Hengstenberg,<sup>9</sup> working in close collaboration with H. Staudinger made the decisive step. (Shortly afterwards, in 1928, Emil Ott, working also with H. Staudinger's substances, came in principle to the same conclusions.<sup>10</sup>) They found the following fundamental facts. The polyoxymethylenes, polymerisation products of formaldehyde, have according to the chemical investigations of H. Staudinger and his collaborators<sup>11</sup> the chemical structure :

a chain form molecule ending on both sides in a hydroxyl group. These hydroxyl groups can either be acetylated or methylated and then can show, e.g. by determination of the number of acetyl groups the length of the chain. It proved to be possible to separate the different polymers from the mixture to such an extent that they seemed to be—on chemical analysis, as specified above—pure chemical substances.

On the other

hand, one can determine the length of the chain by X-ray investigations, and show that it increases proportionally to the number of  $\text{CH}_2\text{O}$ -groups, determined by the chemical method.

FIG. 1.

The main X-ray interferences of these different pure polymers are approximately the same, but there are a few central interferences which differ characteristically with the number of  $\text{CH}_2\text{O}$ -groups present in the polymer. The authors explained this characteristic fact by assuming that the interferences which are approximately the same in all the

polymers are given by the unit  $\begin{array}{c} \text{H} \\ | \\ -\text{C}-\text{O}- \\ | \\ \text{H} \end{array}$  which repeats itself regularly along the chain form molecule. The variable interferences measure

FIG. 2.

the length of the chain, they are the different orders of reflection of this length (or of a quantity directly related with it). Fig. 1 shows diagrammatically the X-ray pattern of a pure polyoxymethylene diacetate (at random distribution of the crystals).  $A_1$  to  $A_4$  are the first to fourth orders of reflection. The length of the molecule, as calculated from the A-interferences, is shown in Fig. 2. As it is a straight line, the length of the molecule as it lies in the crystalline lattice is proportional to the

number of  $\text{CH}_2\text{O}$ -units; therefore this molecule must have, in the crystal, approximately the form of a long straight rod. This X-ray result has to be considered as the first direct experimental evidence of Staudinger's hypothesis, and a decisive one. The length of one  $\text{CH}_2\text{O}$ -group was approximately 1.9 A.U.

These results were obtained with polymethylene diacetates, and with polymethylene dimethyl ethers. By pressing the material the crystals could sometimes be oriented parallel, and therefore fibre diagrams could be obtained; or the material had primarily the fibre form.

While in the case of the lower polymers (for instance, with 10 to 20  $\text{CH}_2\text{O}$ -groups) the length of the molecule could be studied, this method failed in the case of the higher polymers. Here it was not possible to

separate the polymers into fractions having each one single chain length.<sup>12</sup> Such complex mixtures now showed a very interesting phenomenon. *The small interference rings related with the length of the molecule were failing.* This experience is especially interesting, as they have never been found in natural highpolymeric substances (like cellulose, rubber) and many synthetic polymers. So we are led to the assumption that in all such cases where these interference rings fail there are mixed crystals built up by molecules of such a different length that these interferences cannot be formed. Staudinger at once applied these results to cellulose, asserting that it had in principle the same structure.

The publications of Kurt H. Meyer and H. Mark in 1928—see paragraph 2—then brought a second experimental evidence for the hypothesis of a long chain molecule, this time of a more complicated nature. The authors worked out its meaning explicitly for cellulose, rubber, chitin and silk fibroin and made a very important contribution.

The spreading of some high polymeric substances (especially cellulose ethers) in a monomolecular film on a water surface, in films of reproducible thickness and only one hydrocarbon chain thick, which I was able to make in 1928 together with P. J. P. Samwel, may be considered as a third experimental argument for the long chain molecule. The homogeneity of the monomolecular films was doubted; but it was proved to exist in a number of cases by H. Zocher and F. Stiebel.<sup>13</sup> Only their additional research made this experimental evidence fully convincing.

## 2. The Analysis of Crystalline Patterns of Synthetic Polymers.

A number of polymers can show a crystalline pattern; some others have only been found with an amorphous pattern. Some will only give a crystalline pattern when stretched, while they are amorphous in the unstretched form; this latter category we shall discuss later.

There is, however, in principle, no difference in the analysis of a fibre pattern in both cases.

Crystalline polymers are found, for instance, in the case of polyoxymethylenes, polyoxyethylenes, etc. Thiokol (polyethylene-tetra-sulphide), polychloroprene, polybromoprene, polyiodoprene can be found in the crystalline condition, but also in the amorphous state.<sup>14</sup> Moreover, the polyesters, etc., of W. H. Carothers are often crystalline.

In all these cases, when we want to calculate the elementary cell of the crystal, we have to remember the following principles:

(a) When there is a random orientation of the crystals, it is in almost all cases impossible to derive any calculation about the elementary cell.

(b) When we can get all the crystals exactly parallelised, and when they have a sharp lattice, we can get a good fibre pattern. The parallelism can be effected either by stretching or by pressure; in both cases a somewhat plastic condition may be advantageous, or an elastic one in other cases.

<sup>12</sup> See, however, Emil Ott, *Z. physik. Chem.* 1930, **9B**, 378, who studied long chain polymers in which all the molecules seemed to have the same length. In a "paraformaldehyde," e.g., he found a chain length of 60.6 Å.U., for a  $\gamma$ -polymethylene oxide one of 113 Å.U.

<sup>13</sup> J. R. Katz and P. J. P. Samwel, *Naturwiss.*, 1928, **16**, 592; *Ann. Chem.*, 1929, **472**, 241; H. Zocher and F. Stiebel, *Z. physik. Chem.*, 1930, **147A**, 401; N. K. Adam, *Trans. Faraday Soc.*, 1932, **29**, 90.

<sup>14</sup> Thiokol, polychloroprene, polybromoprene can either crystallise spontaneously or become crystallised by stretching. The two kinds of crystals are not necessarily always the same.

(c) In special cases, for instance when stretching very thin films, we may get a higher degree of orientation of the crystals; for instance, not only is a fibre diagram found when such a stretched film is investigated with a primary beam of monochromatic X-rays, perpendicular to the surface of the film, but another regular arrangement will be found when investigated parallel to the surface of the film.

In the case mentioned under (c) there is a higher degree of probability of finding the real elementary cell than in case (b). I have analysed these facts in my book, *Die Röntgenspektrographie als Untersuchungsmethode bei hochmolekularen Substanzen, bei Kolloiden und bei tierischen und pflanzlichen Geweben*.<sup>14a</sup> It seems unnecessary to give here more than a short outline of the discussion given there. Really certain results can only be obtained with macroscopic single crystals; and those cannot be prepared—it seems now—in the case of most substances of a very high molecular weight.<sup>15</sup>

In the cases mentioned under (b) and (c) *it is not possible with real certainty to calculate the elementary cell of the crystal; the only thing we can calculate with full certainty is the period of identity in the fibre axis; but the two axes perpendicular to the fibre axis and the angle between them cannot be calculated with real certainty from a fibre diagram* (even in case (c)). If one investigates, however, for many years one single substance (as R. O. Herzog's school did with cellulose) one can come to a good approximate degree of certainty in the solution one has found. One must be sure to have found *all* the interferences (including the very weak ones) which can be made visible; one must be certain that they are not due to secondary factors, etc.

The uncertainty of this kind of results in other cases, can be best shown by a practical example. H. Mark—certainly one of the best workers in the field—has calculated together with G. von Susich the elementary cell of stretched rubber from the fibre diagram using thin films (see under (c)). He found that the lattice has place for seven isoprene groups, while the number ought to have been eight. In order to reconcile this contradiction, the authors have to assume that pure rubber has a specific weight 10-15 per cent. larger than actually found.<sup>16</sup> All my rubber friends agree with me that such a high specific weight for racked rubber is extremely improbable.

I would, therefore, advise young investigators to be very reticent in undertaking such determinations—unless they are content to get only a *probable* solution of the problem and in their publication explicitly state so—and not to publish until they have studied many fibre diagrams of their substance made under different circumstances.

The elementary cell once "found" we can proceed to the location of the molecules in it, if the structural formula of the organic compound is sufficiently known. This is a still more delicate procedure than the calculation of the elementary cell. It requires a thorough knowledge of crystallography of organic substances to make a good guess, and often—I am sorry to say—is done without an approximate comparison of the relative intensities of the interferences.

In this way we can only come to a probable solution of the problem and no more. If this is duly emphasised in the publication, nothing is

<sup>14a</sup> Berlin and Wien, 1934. Urban and Schwarzenberg.

<sup>15</sup> Compare, however, the large oxyhemoglobin crystals made by M. Arthus and others (7 mm. and over more), e.g. by alcohol dialysis of a solution in water.

<sup>16</sup> H. Mark and G. von Susich, *Koll. Z.*, 1928, 36, 11.

to be said against this procedure. But if it is insufficiently emphasised—as nowadays not rarely happens—then it has the danger of making outsiders give much more credit to these results than they deserve. In this way we are in danger of coming to a construction of results which are not well-grounded and yet materially influence our trend of thought.

On the other hand, it ought to be emphasised that the basic work of this kind on cellulose, rubber, chitin of Kurt H. Meyer and H. Mark<sup>17</sup> in 1928, and the one on polymethylene diacetate, etc., has been an important service to science.

It must not be forgotten that this work of Meyer and Mark has very much contributed to the present day general acceptance of the conception of the long chain molecules, and that it brought to light many other new points of view. These researches have shown us what form the molecules of some of the most important high polymeric substances very probably have and how they probably lie in the elementary cells. Especially in teaching the subject, there is a great advantage compared with the situation ten years ago. We then had to tell our students that we did not understand very much about the structure of these substances. That was very discouraging. Now we can tell them, "look here, *this* is the probable form of the molecule and *this* is their probable place in the crystalline lattice; may be all this is not perfectly certain but it is at least a very good first approximation to the truth, an example how things might be." Where the work so relied on is based on pretty solid ground this is a great advantage in teaching. And not only in teaching but in many other cases where application of this picture of the facts proves useful in colloid chemistry or in industry. It gives us at least a first approximative picture of the truth.

### 3. Results of X-ray Analysis of Crystalline Synthetic Polymerisates.

Except for the polyoxymethylene derivatives where Mie-Hengstenberg<sup>9</sup> and Emil Ott<sup>10</sup> got about the same but slightly divergent results, only a few substances in the group of synthetic polymers have been sufficiently investigated. Here a large field for further investigation lies open. I would draw attention to some interesting conclusions drawn by Edwin Sauter out of the X-ray analysis of polyethylene and polymethylene-oxides.<sup>18</sup>

Especially promising, I believe, is the group of the polyesters synthesised by W. H. Carothers and collaborators, as. *e.g.*, the polyester of sebacic acid and ethylene glycol. As we can systematically vary both the number of carbon atoms of the dibasic acid and of the dialcohol, we could get a homologous series of polyesters. Here the calculation of the two axes perpendicular to the fibre axis would lead to the possibility of a check on the figures got for each of the individual polyesters, by comparison. (Polymorphism would have to be carefully taken into consideration as a possible complication.) Then the results calculated for, let us say, ten or fifteen different polyesters would be far less uncertain than the result calculated for one single term of the series.

The same could be done for analogous substances synthesised by

<sup>17</sup> Kurt H. Meyer and H. Mark, *Ber.*, 1928, 61; for cellulose p. 593; for rubber, p. 1939; for chitin, p. 1928.

<sup>18</sup> Edwin Sauter, *Z. physik. Chem.*, 1933, 21B, 161 and 186.

Carothers, Hill and collaborators, such as polydibasic acid anhydrides, polyamino acids, etc.

This would be a lengthy piece of work, but it might help us, perhaps more than anything else, to understand better than we do now, how much value has to be given to the calculations of the elementary cell and the position of the molecules in it now made more and more for different high molecular weight substances.

#### 4. The Analysis of Amorphous Patterns of Synthetic Polymers.

Here the uncertainty of the conclusions is much greater than in the case of crystalline fibre diagrams. But as in that case, an approximate picture of the truth may be gained, if care and discretion is used in applying the method of analysis.

The analysis of the amorphous polymers seems especially interesting in the case of rubber and other substances which "crystallise" on stretching. We shall come back to this question in paragraphs 6 and 7. The "amorphous unstretched rubber" must contain in its "amorphous" structure in some way (at present not understood) a preformation of the highly parallelised and three-dimensionally ordered structure in which the molecules lie when the rubber has been stretched.

This is the reason why I undertook in 1926 the study of the amorphous patterns of rubber and polymers and compared them with the X-ray patterns of about 400 organic liquids. I hoped by the comparison of both groups of patterns to find a method of approach for the study of amorphous polymerisates.

Unhappily the results of this research have not yet been duly published. A review of the work done on a part of the large number of organic liquids was published in Dutch in J. Selman's doctor's thesis (Amsterdam, 1932). A short review of our work on organic liquids—in an initial state of the work—was published at the beginning of 1928.<sup>10</sup> Many of the results published there were arrived at independently of G. W. Stewart and of C. V. Raman's pupils. On the other hand, their work corroborates and enlarges our collection of X-ray negatives kept for the analysis of amorphous polymers. We came independently to the same conclusion, that the molecules in a liquid lie in parallel groups—each molecule changing constantly from one group to the other—while the axes of these groups lie distributed at random, and that the average form of the molecule is more rigid than was formerly assumed.

As a matter of fact, I have about 400 X-ray patterns of well-chosen organic liquids to compare with the pattern of the polymers; and this comparison often leads to an analysis of the pattern of the polymer. As a simple example of this kind of analysis, let me give an analysis of the four typical types of polymers described by Harries in 1912 in his classical researches on the polymerisation of butadiene, isoprene, and dimethyl-butadiene. Butadiene, isoprene, dimethylbutadiene have, as is known, the structural formulæ:

<sup>10</sup> J. R. Katz, *Z. angew. Chemie*, 1928, 41, 327.

These three liquids give X-ray patterns of the same type; the chief amorphous ring having a period of identity, calculated according to the Bragg formula, of

Butadiene	.	.	.	.	.	.	.	.	4.6 Å.U.
Isoprene	.	.	.	.	.	.	.	.	4.9 Å.U.
Dimethylbutadiene	.	.	.	.	.	.	.	.	5.3 Å.U.

Consulting the patterns of the other organic liquids, we can explain what these numbers mean. The distance, 4.65 Å.U., is the distance we always find for a liquid having straight, not ramified carbon chains as molecules, if this chain is 4 carbon atoms long or longer (however long it may be). It is the same for hydrocarbons, ketones, alcohols, acids, mercaptans (the other group being attached to one end of the hydrocarbon chain). In the picture to which Stewart, Raman's pupils and I have come, this means that in all these liquids the molecules lie in little groups of parallel molecules, the distance of these parallel molecules in the direction perpendicular to the parallelism being just 4.65 Å.U.

Now, if the hydrocarbon or alcohol—having a straight chain of at least four hydrocarbons—has one or two methyl groups as side chains, what do we find? *Just such an increase in distance as we have found for the butadienes*: 0.3-0.4 Å.U. for one methyl group, 0.6-0.7 Å.U. for two methyl groups. In the picture of a liquid to which both Stewart, Raman's pupils and I have come, this means that the increased distance between parallel hydrocarbon chains in the small groups is 0.3-0.4 Å.U. larger for one methyl group, 0.6-0.7 for two.

In this picture, the amorphous patterns of the three liquid butadienes are easily understandable.

Now, if these substances polymerise on being heated, what changes happen in their molecules? According to Staudinger, the following substances are formed:

Butadiene thermal polymer— $\text{CH}_2 \cdot \text{CH}=\text{CH} \cdot \text{CH}_2\text{CH}_2-\text{CH}=\text{CH} \cdot \text{CH}_2-$ , etc.

Isoprene thermal polymer— $\text{CH}_2 \cdot \text{CH}=\text{C} \cdot \text{CH}_2\text{CH}_2 \cdot \text{CH}=\text{C} \cdot \text{CH}_2-$ , etc.

*What kind of amorphous patterns have these thermal polymers? Practically the same patterns as the liquids from which they were polymerised.*<sup>20</sup> For the period of identity of the chief ring calculated according to the Bragg formula, we found:

Butadiene thermal polymer	.	.	.	.	.	4.6 Å.U.
Isoprene	"	"	.	.	.	4.9 "
Dimethylbutadiene	"	"	.	.	.	5.3 "

*An astonishing fact, that these low boiling liquid butadienes almost have the same amorphous pattern as the thermal polymers made from them!* But this is just the consequence of the Staudinger formulæ; just what one would have to expect on the basis of these formulæ. Remember, the distance between the molecules in the groups (perpendicular to the chief chain) is

<sup>20</sup> J. R. Katz, *Z. physik. Chem.*, 1927, 125, 321; J. R. Katz, J. Selman and Lottelise Heyne, *Z. Kautschuk*, 1927, 214.

independent of the length of the chief chain, if this is at least four carbon atoms long.

Now, if we make the three other polymers described by Harries in 1912, what do we find? Harries distinguished the following three polymers:

(a) What we now call the *Kondakow-polymer* (which grows slowly in the liquid in a form resembling a cauliflower, at room temperature).

(b) The *sodium polymerisate*, made by the interaction of metallic sodium on the liquid butadiene.

(c) The *sodium-carbonic-acid polymerisate*, made by the introduction of metallic sodium in a liquid saturated with carbonic acid.

It was found by him and often corroborated by others that (b) and (c) are very different substances; their ozonides, for instance, split with warm water into very different substances. On the contrary, (a), (c) and the thermal polymerisate show a good deal of analogy with one another.

Now, what does X-ray spectrography show? That the Kondakow and the sodium-carbonic-acid polymers have practically the same amorphous X-ray pattern as the thermal polymers, *while the sodium polymers have a totally different amorphous pattern, very different from the liquid patterns*. This corresponds pretty well with the different splitting up of the ozonides of the sodium polymers observed by Harries and with a number of facts described in later years. The X-ray patterns of the sodium polymers seems to show—by comparison with the patterns of certain organic liquids—that the chief straight carbon chain carries a large number of carbon chains which must be longer than one carbon atom. Some facts from organic chemistry seem to point in the same direction.

In the same way the phenol-formaldehyde polymers might be analysed by comparison with the liquid patterns of the phenols, especially if the side chains of the phenols are systematically varied. R. Houwink has already begun to make an investigation of this kind.<sup>21</sup> Here, as Kurt H. Meyer and H. Mark first emphasised, the molecule might have the form of a large flat disc.

The more I have had the opportunity to study amorphous polymers of different kinds, either from a scientific or from a technical point of view, the more I have found the comparison with the patterns of a large number of organic liquids a fruitful method. In the course of years one learns to build out one's collection of organic liquids in the direction in which one wants it.<sup>22</sup> And generally one is able on this basis to give an interpretation of the amorphous pattern of the polymer.

<sup>21</sup> R. Houwink. *Physik. Eigensch. u. Feinbau. v. Natur- u. Kunstharzen*, Leipzig, 1934.

<sup>22</sup> In recent years B. E. Warren has developed a somewhat different method of analysis of liquid patterns than Stewart, Raman's pupils and I have used. The pattern taken up in *vacuo* with purely monochromatic light is analysed by the photometer and the intensity curve analysed by Fourier analysis. An application of this method to the analysis of the amorphous pattern of rubber has just been announced (see *Physical Review*, 1935, 47, 808), but not yet published at sufficient length to compare it with our conception. It shows in principle three periods of identity to exist in the rubber, the period of 4.9 Å. mentioned above is interpreted as the shortest distance of a carbon atom from the next carbon atom of an adjacent chain, the two others as intramolecular periods of identity (of a carbon atom to the next, on to the next but one carbon atom of the chain). Warren's method is, I believe, a very promising one.

### 5. Amorphous Patterns of Synthetic Polymers.

In the case of a number of polymerisations the amorphous pattern of the polymer is not simply the same as in the non-polymerised liquid. It can be different, according to our observations in the year 1927, and in two different ways.<sup>23</sup>

(1) Either it is entirely different—as already described for the sodium polymers of the butadienes; this behaviour is found in polymerisation of vinyl acetate to polyvinyl acetate, or of methyl acrylate to polymethyl acrylate; or

(2) All the interferences of the liquid are found again in the amorphous pattern of the polymer, but one ring of small diameter is added, which I have called the *polymerisation ring*. This behaviour is found in styrene-polystyrene; cumarone, polycumarone; indene, polyindene. Liquid styrene, for instance, has an amorphous ring  $d = 4.85$  Å.U., metastyrene the same ring  $d = 4.85$ ; but, in addition, a small ring  $d = 10.0$  Å.U. (Figs. 3 and 4). Just so liquid indene has an amorphous ring  $d = 5.15$  Å.U., while polyindene has the same ring, but in addition a small ring  $d = 10.1$  Å.U.

FIG. 3.—Styrene.

FIG. 4.—Polystyrene.

It has been difficult, for a long time, to understand the meaning of this polymerisation ring. In the case of polystyrene, however, it has been cleared up a good deal in the course of the last year by the fact that C. S. Fuller and I were able—by stretching polystyrene without making it crystalline—to split the polymerisation ring into two equatorial maxima.<sup>24</sup> This seems to indicate, as in the case of the splitting of the mesomorphic ring of *p*-azoxyanisole in a magnetic field, that the long molecules are oriented by the stretching, with their longest direction in the direction of the stretch. According to Staudinger polystyrene must have the formula

The distance between two parallel chains might easily be 10.0 Å.U.

<sup>23</sup> J. R. Katz, J. Selman and Lottelise Heyne, *Z. Kautschuk*, 1927, 217; *Z. physik. Chem.*, 1927, 125, 321.

<sup>24</sup> Probably Miss M. Hühnemörder, *Z. Kautschuk*, 1927, 106 and 126 has made the same observations as we. But I am not sure that her patterns do not show a change through stretching which goes further than ours, perhaps incipient crystallisation.

In the liquid benzene derivatives the flat benzene rings probably lie like a roll of coins on one another; we must assume, as all the interferences of the liquid styrene are found again practically unchanged in the polystyrene, that the flat benzene rings lie very much in the same way in the amorphous polymerisation product. But because of the polymerisation a new period of identity is found, which we have tried to explain in the above-mentioned way.

A very interesting change of the amorphous patterns through stretching is observed when stretching certain samples of polyvinyl acetate. At room temperature they are resinous, at 100° C. the substance is elastic like a piece of rubber. When stretched the substance does not "crystallise," but the inner one of the two amorphous rings develops two equatorial intensity maxima (Fig. 5). This inner ring has a  $d = 7.05$  Å.U. According to the theory of Staudinger the formula of polyvinyl acetate is probably

FIG. 5.

As the inner ring develops two equatorial maxima of intensity on stretching, probably the chief chains orient themselves parallel to the direction of the stretch. The distance 7.05 may correspond to the distance between the two parallel hydrocarbon chains. The outer ring  $d = 4.05$  Å.U. is more difficult to explain—perhaps it is the distance between adjacent acetyl side chains.

Queerly enough, many polymers, for instance, isoprene thermal polymer, polymethyl acrylate, etc., do not show any change in their X-ray pattern, an amorphous one, when they are stretched. Such substances should, however, once stretched, be cooled down at once in liquid air and be investigated at its temperature. The relaxation then would be prevented, and one may perhaps observe a change in X-ray pattern which now escapes us.

## 6. "Crystallisation" of Amorphous Rubber when Stretched as a Comparison for Synthetic Substances which Behave in an Analogous Way.

Before describing the X-ray phenomena observed when synthetic polymers with a rubber-like elasticity are stretched, it is necessary to describe shortly the X-ray phenomena which have been observed in the stretching of natural rubber. In these synthetic substances frequently the "crystallisation" phenomena are not so fully developed; they are more rudimentary than in the natural substance. We shall in the next paragraph try to indicate how and why.

In 1924, while playing with an ordinary rubber band, I accidentally observed that it was transparent when unstretched and regularly became opaque when stretched. I made a wild guess: something unmixed and

becomes opaque like a phenol-water mixture which is cooled off. So I made an X-ray experiment and really found that a new "phase," in the sense of the phase rule, was formed by stretching the rubber. *This phase is a "crystalline" one* and all the little "crystals" are parallel (with the same crystallographical axis) to the direction of stretch. The X-ray pattern of the unstretched rubber was "amorphous," while that of the stretched rubber was a "crystalline" fibre pattern,—superimposed over a weakened amorphous ring.

The fibre pattern shows, moreover, that the rubber must have acquired a fibre structure by being stretched. And that this was the case was also shown by L. Hock by freezing the rubber in liquid air and then hammering it; the fissures will all lie in the direction of the stretch, while in unstretched rubber they will lie distributed at random.<sup>24a</sup>

In stretching the rubber I found there was a *critical stretch* (about 80 per cent. elongation for unvulcanised rubber). A smaller elongation will never produce any "crystalline" interferences; above this critical elongation the intensity of interferences will be the greater the larger the

FIG. 6.

FIG. 7.

elongation. In these elongations below 80 per cent. the rubber molecules get already oriented in the direction of the stress; but they do not yet "crystallise": arrange themselves into a three-dimensional lattice.

This "crystallisation" I concluded must be the chief component of the Joule heat of rubber, the heat developed by rubber when stretched (as every transition of amorphous to crystalline must give a good deal of heat).

These X-ray phenomena of stretched rubber I first described and developed in two journals which are not much read in England and America.<sup>25</sup> My experiments were soon confirmed and further developed by other authors.<sup>26</sup>

<sup>24a</sup> L. Hock, *Z. Elektrochemie*, 1925, 404; *Z. Kautschuk*, Oct., 1925.

<sup>25</sup> *Naturwissenschaften*, 1925, 13, 411; and *Gummi-Zeitung*, 1927, 41, Nos. 36 and 37.

<sup>26</sup> E. A. Hauser and H. Mark, *Kolloidchem. Beihefte*, 1926, 22, 88; G. L. Clark, *J. Ind. Eng. Chem.*, 1926, 18, 1131.

The arrangement and parallelisation of the rubber molecules below the critical elongation was investigated at my instigation by W. C. van Geel and Miss J. G. Eymers.<sup>27</sup> Below the critical elongation the optical anisotropy depends (through an S form curve) on the elongation; then there is a sharp break, a real discontinuity in the curve: and above the critical elongation the optical anisotropy is strictly proportional to further increase in elongation (Fig. 6).

The heat developed through the "crystallisation" is zero till the critical elongation is reached. Then it is strictly proportional to the further increase in the elongation (L. Hock and S. Boström).<sup>28</sup> (Fig. 7). The intensity of the "crystalline" interferences depends in the same linear way on "the amount of elongation above the critical point" (E. A. Hauser and H. Mark).<sup>29</sup>

## 7. Rubber-like Synthetical Substances which "Crystallise" when Stretched.

### (a) Polyvinyl Alcohol.

Several amorphous polymers have been studied lately which give a good fibre diagram on being stretched. *Polyvinyl-alcohol* in a certain state of polymerisation at a certain temperature was described as giving a perfectly sharp fibre diagram when stretched (F. Halle). A picture of the fibre diagram is given, but further details are lacking in the preliminary publication.<sup>30</sup> It would be especially valuable to know if there is a sharp critical elongation, and if curves Figs. 6 and 7 are the same for polyvinyl-alcohol as for rubber.

### (b) Polyethylene Tetrasulphide (thiokol).

C. S. Fuller and I studied recently<sup>31</sup> the X-ray pattern of *polyethylene tetrasulphide (thiokol)*. From the as yet unpublished article I may quote the following facts. It is generally found "frozen," that is to say, crystalline; it is then hard, brittle, inelastic. When heated above 70° C. it melts, and then becomes an elastic rubber-like substance, used in industry because it is a rubber-like body which is resistant against oil and organic solvents. It is made by interaction of  $\text{ClCH}_2 \cdot \text{CH}_2\text{Cl}$  with  $\text{Na}_2\text{S}_4$ , and forms a polymer (much in the same way as Carother's polyesters) having the empirical composition  $[\text{CH}_2 \cdot \text{CH}_2\text{S}_4]_n$ , where  $n$  is a very large number.

In the frozen condition it has a crystalline pattern; in the unstretched rubber-like form it has an amorphous pattern consisting of two amorphous rings ( $d_1 = 10 \text{ \AA.U.}$ ,  $d_2 = 4.65 \text{ \AA.U.}$ ).

When stretched, the substance behaves like rubber. It then gives a beautiful crystalline fibre pattern, having very sharp interference spots. The period of identity  $b$  in the direction of the fibre axis is  $4.32 \text{ \AA.U.}$ , or probably double this. Treated with a 10 per cent. sodium sulphate solution, one half of its sulphur is taken away. It then has the composition  $[\text{CH}_2\text{CH}_2\text{S}_2]$ ; this has a period of identity in the fibre axis twice as

<sup>27</sup> W. C. van Geel and J. C. Eymers, *Z. physik. Chem.*, 1929, B3, 240.

<sup>28</sup> S. Boström, *Kolloidchem. Beihefte*, 1928, 26, 439.

<sup>29</sup> E. A. Hauser and H. Mark, *loc. cit.*

<sup>30</sup> Fr. Halle, *Kolloid. Z.*, Dec., 1934.

<sup>31</sup> During my stay as a Baker non-resident lecturer in Cornell University in the first term of 1934-1935.

large. We tried to calculate the elementary cell and found as a possible solution a monoclinic space lattice

$$\begin{aligned}a &= 8.68 \text{ \AA.U.} \\b &= 8.64 \text{ \AA.U.}, \text{ or } 4.32 \text{ \AA.U.} \\c &= 5.03 \text{ \AA.U.} \\\beta &= 87^\circ,\end{aligned}$$

in which two, or one group  $\text{C}_2\text{H}_4\text{S}_4$  is present per unit cell; these figures have to be taken with all the reserve mentioned in paragraph 2. The unit cell probably has the larger size and contains two  $\text{C}_2\text{H}_4\text{S}_4$  units; but no interferences have so far been found in the tetrasulphide, forcing us to make this assumption.

Important evidence can, however, be drawn from the value  $4.32 \text{ \AA.U.}$ , found for the period of identity in the fibre axis. Two formulae seem possible for the polytetrasulphide. Either it is

or

The X-ray pattern forces us to give up the first formula and to accept the second; the unit of the first is far too long to fit in the dimension  $4.32 \text{ \AA.U.}$ , while  $\text{CH}_2-\text{CH}_2-\text{S}-\text{S}$  just fits in well. The two other sulphurs must then be loosely attached, not forming a part of the chief valency chain. This corresponds very well with Patrick's observation, that one half of the sulphur can be easily taken away as by a 10 per cent. sulphite solution. This disulphide has a period of identity in the direction of the fibre twice as great as the tetrasulphide.

In the polyethylenesulphide series we have again the same advantage as in the polyester series mentioned in paragraph 3. Instead of ethylene, Patrick has furnished us with methylene or propylene, giving polymethylene-tetra-sulphide or polypropylene tetrasulphide. If our lattice is well calculated, there ought to be logical changes when comparing these substances. The sulphur content can, moreover, be made larger or smaller, oxygen can be added, etc., so a good check on the lattices calculated is possible.

We are now working on this programme. Determinations of the critical elongation, or like Figs. 6 and 7, have not yet been made, but will be made soon.

### (c) Polychloroprene (Du Prene) and Polybromoprene.

Kenney<sup>32</sup> has found that these substances are amorphous in the unstretched condition, while they have a crystalline fibre diagram superimposed over a weakened amorphous ring when it is stretched. The period of identity in the fibre axis is  $4.9 \text{ \AA.U.}$ , showing that we have to do with a *trans*-form like gutta-percha hydrocarbon and not with a *cis*-form like rubber hydrocarbon (the unit would then have an approximate length of  $4.1 \text{ \AA.U.}$ ).<sup>33</sup> *Polychloroprene therefore is a derivative of gutta-percha hydrocarbon and not of rubber.*<sup>32</sup> The fibre pattern has a characteristic property: while the equatorial interferences are very sharp, the layer

<sup>32</sup> See W. H. Carothers, I. Williams and J. S. Kirby, *J. Amer. Chem. Soc.*, 1931, **53**, 4203-25.

<sup>33</sup> According to the conception of Kurt H. Meyer and H. Mark.

line interferences have a varying degree of unsharpness; there is probably some further complication in the problem than we have stated above. I have made many X-ray pictures of these substances and can corroborate these observations and conclusions out of my own experience. I hope soon to come back to these substances in an explicit publication.

**(d) Methyl Rubber** (*thermal polymer of  $\beta\gamma$  dimethylbutadiene*).

This substance gives—as we have shown in 1927<sup>34</sup>—a fibre diagram on stretching; but this diagram was not fully developed. The sharpness of the fibre pattern depends on the sample of methyl rubber investigated. L. Hock using another sample did not find any crystallisation on stretching when he worked at room temperature, but only when he cooled the sample.<sup>35</sup>

**(e) Isoprene Rubbers.**

Isoprene rubbers have never given, so far, any sign of crystallisation when stretched, not even a change in their amorphous rings. Perhaps, however, they ought to be investigated at low temperature, or better be cooled immediately after they have been stretched.

**(f) The Synthesis of Rubber out of Isoprene has not yet been made.**

As no isoprene rubber has so far given any sign of crystallisation when being stretched; as this "crystallisation" on stretching is one of the most characteristic qualities of rubber, I still maintain—as I did in 1920—that *the synthesis of natural rubber has not yet been achieved*.<sup>36</sup> Synthetic isoprene rubber is yet a different substance from natural rubber. Steinmig was probably right in 1912 when he predicted that natural rubber would never be synthesised, because we cannot achieve a regular sequence of the methyl groups in the synthetic product. In polychloroprene and polybromoprene the activity of the molecules due to the Cl or Br may make this regular attachment more easy. But is the lack of sharpness of the layerlines due to the cause as Steinmig indicated, but working to a minor degree? Or to alternations of *cis* and *trans* units? Butadiene rubbers will always be found in forms which crystallise on stretching as their molecules have no side chains.

**(g) Synthesis of Rubber ought to be done under X-ray Check.**

As the "crystallisation" on stretching is a typical quality of any good rubber-like material the synthesis ought to be worked out so that the material gets a better and sharper fibre pattern on stretch.

Especially for the industrial production of butadiene rubber this may prove, I think, an important method for the improvement of existing types of synthetic rubber. As conditions are forcing more and more countries (e.g. Russia, Germany) to prepare a part of the rubber they need synthetically, this point of view seems to me to be again of considerable materiality.

"Crystallisation" of rubber or rubber-like substances on stretching is such an extremely characteristic property of them, that where it is

<sup>34</sup> J. R. Katz and P. van Campen, *Chem. Z.*, 1927, **51**, 53. Good pictures of these X-ray patterns in my book, *Die Röntgenspektrographie als Untersuchungsmethode bei hochmolekularen Substanzen*, etc. p. 150.

<sup>35</sup> *Z. physik. Chemie*, 1928, **134**, 271.

<sup>36</sup> J. R. Katz, *Ist die Synthese der Kautschuks schon gelungen? Ambion-Festschrift* (Koll. Beih.), 1920, 341.

defective something essential is lacking in the molecular structure of the rubber (see the next paragraph, however).

### 8. Spontaneous Crystallisation of Natural Rubber and of Synthetic Polymerisates ; their Melting-Point.

In addition to the "crystallisation" on stretching, both natural rubber and some of the synthetic substances with a rubber-like extensibility show another form of crystallisation, this time a real and spontaneous one. When kept at a well-chosen low temperature—different for each substance—its amorphous pattern is changed into a crystalline pattern. At the same time it loses its transparency, becomes hard and inelastic ; it ceases to have a rubber-like extensibility. If the amorphous substance is cooled down too far (e.g., in liquid air), it will not crystallise, evidently because the velocity of crystallisation has been too much reduced. When the once crystallised substance is heated, it often has a pretty sharp melting-point.

In two cases—natural rubber and thiokol—it has been shown that the melting interval is quite short. Samples were kept for some time (e.g., a day) in thermostats at constant temperature, then examined shortly afterwards, both with X-ray spectrography and for specific weight, hardness and transparency. They were found to have a fairly sharp melting-point, the melting interval being in both cases only a few degrees.<sup>37</sup>

In the case of natural rubber the melting-point seems to vary with the age of the crystalline rubber ; in the case of thiokol this was not found. In old natural rubber it lies at about 36° C., in thiokol at about 70° C.

In natural rubber the interesting fact was found that the X-ray pattern found by the spontaneous crystallisation shewed the same lattice as the one formed by stretching. This fact makes it difficult to understand why the crystalline pattern once formed by stretching disappears again when the stretched rubber is relaxed.

### 9. Explanation of the X-Ray Phenomena of Rubber and of Rubber-like Substances.

The following facts have also to be taken into account, before considering an explanation as valid :—

#### (a) The Substances which show a Rubber-like Extensibility.

The organic substances which show rubber-like extensibility seem all to have a long chain molecule. They are :

*α. Organic polymerisation made of unsaturated compounds :* Butadiene rubbers, polychloroprene, polybromoprene ; metastyrene ; polymeric methyl or ethyl ester of acrylic acid ; polymeric vinylacetate ; and polyvinyl alcohol.

*β. Certain swollen proteins :* Gelatin swollen in water, or in water-alcohol, or in water-glycerin ; silk fibroin swollen in formic acid ; collagen swollen in certain swelling agents ;  $\alpha$ -keratin, swollen in water, especially after stretching and relaxation.

*γ. Perhaps, cellulose, swollen in sodium hydroxide solutions, and certain cellulose derivatives swollen in organic compounds.*

<sup>37</sup> For rubber, see J. R. Katz and K. Bing, *Z. angew. Chem.*, 1925, 38, 439 ; A. van Rossem and J. Lotichius, *Z. Kautschuk*, 1929, 5, 2 ; J. R. Katz, *ibid.*, p. 8. For thiokol see J. R. Katz and M. T. Bush (*not yet published*).

Moreover, there are some *inorganic* rubber-like substances, *e.g.*, *sulphur* and *polymerisation products of  $PNCl_2$* ; probably these inorganic substances also have a long chain molecule.

**(b) All these Rubber-like Substances have some Typical Characteristics.**

- $\alpha$ . They develop heat when stretched (like the Joule heat of rubber).
- $\beta$ . They show fibre structure when stretched and frozen in liquid air; the fissures on mechanical treatment all run parallel to the direction of the stretch.
- $\gamma$ . They show, especially when they "crystallise" on stretching, a characteristic stress-strain curve comparable with that of natural rubber.
- $\delta$ . They show optical anisotropy when stretched, depending in characteristic curves on the degree of stretching.

**(c) In all these Substances the Rubber-like State only Exists Within a more or less Narrow Range of Temperatures; Swelling Reduces these Temperatures.**

The upper temperature is the one where the elastic substance becomes plastic; it is not generally sharp. The lower limit—called in 1915 by Ostromyslen-ski the "dead temperature"—is the temperature where the rubber changes into a resin. It is accompanied—as Martin Ruhemann and F. Simon have shown—<sup>38</sup> by a large drop in the value of the specific heat; this drop is analogous to the drop in specific heat when liquid glycerin is changed by cooling into a glass. The "dead temperature" again is a temperature interval which, however, may be quite short (*e.g.*  $10^\circ$ ).

If a liquid which swells the rubber-like substance is added, the "dead temperature" is decreased even to a large extent. The *elasticators* of Hofmann (dimethylaniline, dibenzyl ether, etc.) were well known to have this effect in the case of methyl rubber (heat polymerisate of *β*-dimethylbutadiene). As a matter of fact the methyl rubber acquired a sufficient elasticity only after the addition of an elasticator. That gelatin, silk fibroin, etc., acquire rubber-like elasticity only after being strongly swollen is again an "elasticator effect," but a very much stronger one than in the case of methyl rubber.

**(d) In the Case of Natural Rubber, the Discontinuity in the Curve of the Optical Anisotropy as a Function of the Elongation shows that there are Two Phases in the Stretching of Rubber.**

In the first phase the molecules are oriented into the direction of the stretch and perhaps stretched; but they do not yet form a three-dimensional arrangement. In this part of the curve the optical anisotropy increases according to an S-form curve (as in a nematic phase when its molecules are oriented parallel by a magnetic field); see Fig. 6.

*The critical elongation is the stretch, where the initially parallel molecules are forced into a three-dimensional arrangement.* As the stretch increases, more and more bundles of molecules are forced into this three-dimensional arrangement, *i.e.*, are forced to reach their critical value.

This formation of crystals may have to do with the characteristic form of the stress-strain curve of rubber, specially with the fact that the

<sup>38</sup> Martin Ruhemann und F. Simon, *Z. physik. Chem.*, 1928, **128**, 1.

elasticity at a certain stretch is almost exhausted. Mallock explained this fact long ago in connection with the resistance of putty to stretching. When the oil film between the chalk particles gets too thin, the putty is not stretched so easily as at first, "it stiffens up."

### (e) Conclusions.

All these facts have to be explained before we can accept a theory for the rubber-like elastic extensibility as valid. There are two conceptions possible, *either* we consider the rubber molecule itself as the structure which is stretched and retracts; stretching then converts the coiled-up molecule into a straight one, *or* we assume that the structure which gives the rubber-like extensibility is larger than a molecule.

As the second hypothesis could not be worked out in a good form, one has turned more and more to the first. It would serve to explain the X-ray phenomena on stretching of rubber, and it seems in many other respects probable. But there are two difficulties. The one is that we do not see why a rubber once crystallised by stretching should become amorphous again on relaxation at a temperature far below the melting-point of spontaneously frozen rubber. Secondly, we do not see what force is strong enough to retract the rubber, no matter how carefully we observe. E. Mack has tried to explain it by the attraction of hydrogen atom to hydrogen atom; others by appealing to the Brownian movement of the chain (Kurt H. Meyer and others). Both conceptions seem possible, but no really convincing argument, I think, has as yet been given. So we cannot yet offer a really good explanation of the rubber-like elasticity and of the X-ray spectrographical facts so closely connected with it.

The same difficulties in the explanation of the X-ray phenomena and the elasticity are met in synthetic substances with a rubber-like extensibility.

### GENERAL DISCUSSION

**Professor K. H. Meyer** (Geneva) said: "Speaking of 'probability' and 'certainty' in the determination of elementary cells and spacial models, let me emphasise, that the cell dimensions of cellulose," rubber," and silk fibron<sup>40</sup> have been based on diagrams with subjects of a higher order of orientation. Such subjects, generally thin films, show an orientation not only parallel to the fibre axis, but also in the plane perpendicular to this axis. One can therefore calculate with full *certainty* the three density periods and the elementary cell.

As to the abnormal specific weight, which follows from the dimensions of the rubber cell of Mark and Susich, recent experiments in Geneva showed, that this discrepancy is due to a simple experimental error.

From a general point of view, I desire to observe in regard to the "probability" or "certainty" of our spacial models, that Katz only takes into account the Roentgenographical arguments and we quite agree, that with these data alone one cannot attain practical certainty in such complicated molecules. But if one takes into account the chemical evidence, for instance the cellulose and cellulose formula of Haworth and the rubber formula of C. O. Weber in connection with other physical properties (*e.g.*, tenacity, double-refraction, etc.) one arrives at only one possible, and therefore final solution, in which only slight variations of the atomic parameters can be allowed.

**Professor H. Mark** (Wien) said: Dr. Katz's contribution gives the impression that the ideas on the structure of such highly polymerised substances as cellulose, rubber, keratin, etc., are as yet not at all well

<sup>39</sup> Mark and Susich, *Z. physik. chem.*, 1929, **4B**, 431.

<sup>40</sup> Mark and Susich, *Koll. Z.*, 1928, **46**, 11.

<sup>41</sup> Kratky, *Z. physik. chem.*, 1929, **5B**, 297.

founded on actual experiment. He therefore speaks of the "hypothesis" of the long chain model and points out, that it is mainly of importance for teaching, and not so much for research.

I think we may justifiably attribute to these models (which have been worked out during recent years with increasing accuracy by a large number of authors), a somewhat high degree of truth. I quite agree with Dr. Katz that we must needs improve our ideas here and there, work out the exact positions of the different atoms in the lattice, and explore the accurate dimensions and shape of the molecules in solution, but I am quite convinced that the present point of view will not be totally changed, so that we shall have to start to work in quite another direction. The increasing confidence given to our present models of long-chain molecules is based, not so much solely on the work on highly polymerised substances, as on the facts that, during recent years, we have learned a great deal about the solid state, and that our general knowledge of the structure of organic crystals has considerably increased. This very important development is, in the first place, due to the systematic work of Sir W. H. Bragg and Professor W. L. Bragg and their collaborators, and was carried out mostly in the Royal Institution in London, in the Physical Laboratory in Manchester, and in the Mineralogical Institute in Cambridge. It is well known that, by considerably improving experimental methods, and working out quite new means of evaluating the relative and absolute intensity measurements, one is now able to fix the atomic positions, even in very complicated lattices, such as, e.g., hydroquinone, dinitrobenzene, chrysene, etc. In the case of the cellulose, Andress and von Susich have carefully measured the relative intensity of all interference spots, and Hengstenberg has strengthened their calculations by the measurement of the more important absolute intensity values. These figures were evaluated by the normal method of structure factor, and led to the present conception as to the positions of the different atoms in the unit cell. To bring the situation up to date, it would be necessary to apply the Fourier's analysis method to these experimental data, which would of course be a very important task. It is quite probable that such a calculation would change the position of different atoms in the lattice, and bring about a closer agreement with the experimental facts, but I do not think that a fundamentally different structure would be derived.

At this stage it is important to point out, that it is not by any means the X-ray evidence alone which leads to our present conception of the structure of high polymeric substances. A large number of independent arguments come from investigations in organic chemistry and physical chemistry, which lead to exactly the same result. I mention the synthesis of main valence chains by Staudinger and his co-workers, the degradation of cellulose by Freudenberg, Haworth and their collaborators, the preparation of several new addition compounds by Hess and Tregus, and the investigation of different physico-chemical properties by Berl, Herzog, Katz, Kraemer, Mark, Meyer, Ostwald, Signer, Svedberg and a number of other authors. All these studies, starting from quite different directions, converge in their results upon a model which can surely be called a very good approximation to the truth, and can be regarded as a trustful basis for future work.

I would like to recall that the diffraction of electrons on high polymeric substances, which has been investigated by Dauvillier, Kirchner, Mark, Motz, Taylor-Jones and Trillat offered at first very serious difficulties to the long chain model of cellulose. In the end Mark and Trillat and at the same time Hengstenberg and Wolt gave vent to the suspicion, that the very sharp interference spots obtained with these substances are not due to cellulose, but may be caused by an impurity. Accurate measurements of Mark, Motz, Natta and Trillat showed later that, in fact, these patterns are produced by grease-like substances, which are extended on the surface of the films in very thin layers. If one removes these films, the diagram

vanishes, if one produces them the diagram appears. The same has been found on metallic films, and may serve to explain several features, which are not yet quite clear.

On the other hand, I quite agree with Dr. Katz, that one must be very careful, in drawing conclusions from fibre diagrams and, to a still higher degree, from ring diagrams. Everybody who uses the X-ray method in the field of high polymeric substances (and is therefore forced to interpret interference patterns of diagrams which often show only a few points or rings) should work out at least one structure in the field of normal organic lattices, because only in doing this can he get the experience, which seems to be indispensable if one wants to evaluate diagrams of high polymeric specimens. I agree also with Dr. Katz, that one should, with great caution, apply results derived from diagrams with few spots or rings, and I do not think that it is possible to clear up the exact shape of molecules in a liquid by measuring the diameter of only two diffuse rings.

**Dr. R. Houwink** (*Eindhoven*) said: May I point out, in variance with Dr. Katz' opinion, that not all organic substances which show rubber-like extensibility seem to have a long-chain molecule. In this connection I refer to my paper,<sup>42</sup> on the high-elasticity of three-dimensionally polymerised materials.

**Dr. W. H. Carothers** (*Wilmington*) said: Linear condensation polymers of simple unsubstituted types are almost invariably sufficiently crystalline to furnish well-defined powder diffraction patterns, and they can also usually be got in a form suitable to yield fibre patterns as well. Since with relatively few starting materials the length of the unit  $A-B$  in the chain  $A-B-A-B-A-B$ , etc., can be varied at will over a very wide range, such polymers furnish a vast family of excellent models for the study of X-ray behaviour. As yet they have received relatively little attention. It is a curious fact also that in some cases sharp patterns can be obtained from a mixture of reactants  $A$ ,  $B$ ,  $A'$ ,  $B'$ . This leads to four structural units  $A-B$ ,  $A'-B'$ ,  $A-B'$ , and  $A'-B$ , all of different lengths, and since they must be arranged at random in the polymer chains, the probability of finding two identical molecules of say 50 units in a sample of moderate size is very small. The co-existence of crystallinity with such a degree and type of heterogeneity seems difficult to reconcile with the conventional ideas of crystallinity.

# THE FORMATION OF HIGH POLYMERS OF UNSATURATED SUBSTANCES.<sup>1</sup>

BY PROFESSOR DR. H. STAUDINGER, *Freiburg i.Br.*

*Communication No. 120 in the series "Über hochpolymere Verbindungen."*

*Received in German 29th July, 1935, and translated by DR. E. RABINOWITCH.*

## I. Influence of the Substituents upon the Polymerisation-Capacity of Unsaturated Compounds.

A great number of unsaturated compounds, containing a C=C double bond or a carbonyl-group<sup>2</sup> have the tendency to polymerise—i.e., to transform themselves into substances of unchanged composition but with a much higher molecular weight. The strength of this tendency is very different with different compounds and depends essentially on the nature of the substituents adjacent to the double bond. Ethylene, for instance, is a stable compound, whereas its derivatives containing "negative" substituents are unstable and easily polymerised, e.g. styrene, vinyl chloride, vinyl acetate and acrylic ester. The influence of the same substituents is different in the case of the C=C double bond and in that of the carbonyl-group. In the latter case, the simplest compound, formaldehyde, is the least stable of all. The introduction of phenyl and especially of chlorine into the molecule of formaldehyde cause the tendency to polymerisation to disappear. (Benzaldehyde and phosgene for instance are stable compounds.) The substitution of

<sup>1</sup> Compare the author's monograph *Die hochmolekularen organischen Verbindungen-Kautschuk and Cellulose*, Springer, Berlin, 1932. Quotations "Book, at p. " below refer to this monograph.

<sup>2</sup> We do not discuss in this paper the polymerisation of substances whose unsaturated groups are other than C=C, e.g. such as C=N or C=S.

a carbonyl or a carboxyl group makes the molecule unstable again—as shown, *e.g.* by glyoxylic acid, glyoxal and methyl glyoxal. Table I. summarises the results.

When more than one substituent is present in an ethylene derivative, one usually finds that the symmetrical compounds are more stable than the asymmetric ones. The asymmetric ethylene dichloride polymerises for example much more readily than the corresponding symmetric compound: for instance crotonic ester is stable, the methacrylic ester is not.<sup>3</sup>

Unsaturated compounds with conjugated double bonds are generally more reactive than those with isolated double bonds. Butadiene, for instance, polymerises much more easily than ethylene or ethyl-ethylene, acrolein much more readily than propionic-aldehyde. If a methyl group is introduced into a molecule with conjugated double-bonds with  $\alpha$ -position, the polymerisation-tendency becomes weaker; it is raised, however, by the same substituent in a  $\beta$ -position.

The polymerisation of some unsaturated compounds occurs spontaneously even at or slightly above room temperature. Formaldehyde, styrene, and acrylic ester provide examples of this behaviour. Polymerisation is often favoured by light, as in the cases of vinylacetate and particularly of vinyl chloride and vinyl bromide. Many unsaturated compounds polymerise only with catalysts. An appropriate catalyst is Florida-earth; halogenides of metals or non-metals possessing a tendency to form complexes are also good catalysts, *e.g.*, boron fluoride, tin tetrachloride and aluminium chloride. Silicon tetrachloride and phosphorus oxychloride, although belonging to the same class of acid chlorides, have no tendency to form complexes and therefore do not strongly catalyse polymerisation-reactions.<sup>4</sup> Among the unsaturated compounds which polymerise only with catalysts are *iso*-butylene, anethole and indene.

Some polymerising unsaturated substances form dimeric, trimeric, sometimes tetrameric products—examples are diphenyl-ethylene, diphenyl-ketene, phenyl-*iso*-cyanate; others give high polymers, *e.g.*,

<sup>4</sup> Cf. H. Staudinger and H. A. Bruson, *Annalen*, 1926, **447**, 110.

vinyl chloride, vinyl ester, vinyl acetate. A certain number of unsaturated compounds yield low or high polymers according to the polymerisation conditions—it is for instance possible to convert styrene into distyrene by certain catalysts,<sup>6</sup> whereas the spontaneous polymerisation of styrene—or polymerisation catalysed by other substances—yields highly polymerised “poly-styrenes.” Dimethyl ketene and cyclopentadiene give dimolecular products by spontaneous polymerisation; by addition of catalysts it is possible to obtain high polymers of these substances too.<sup>6</sup>

## II. The Importance of Synthetic High-Polymers.

In the following, polymers of the ethylene derivatives and of carbonyl-compounds alone will be considered. Among all the synthetic high polymers they offer remarkable scientific and technical interest.

Many of them have been investigated from the *scientific* point of view because of the analogies they offer to many natural high-molecular products and their derivatives. They dissolve with strong swelling and form colloidal solutions; they belong thus to the class of lyophilic colloids. It was found of great advantage to use synthetic products of this kind, because of their relatively simple structure and their greater stability, for studying the colloidal properties in general. By investigating the chemical constitution of synthetic high-molecular substances it was found that their colloidal properties—such as swelling capacity and viscosity of their solutions—depend only upon the size and shape of their macro-molecules. These experiments led to valuable conclusions as to the structure of natural high-molecular products, for instance of caoutchouc<sup>7</sup> and cellulose,<sup>8</sup> which are built-up in the same manner as the synthetic high polymers. The colloidal properties of these natural products are also functions of the size and form of their macro-molecules.

The synthetic high polymers, which are obtained by polymerisation of unsaturated compounds, offer great interest also from the technical point of view. Since many of their properties are similar to those of the high-molecular natural products, they can be used as more or less complete substitutes for them. It is not improbable, that sooner or later a way will be discovered to prepare artificial fibres from synthetic high-molecular products, because the strength and elasticity of natural fibres depend exclusively on their macro-molecular structure—i.e., on their long thread-shaped molecules. Industry is therefore keenly interested in the investigation of the constitution of high-molecular products and of the nature of the polymerisation process.

## III. Homœopolar and Heteropolar Molecular Colloids.

The aim of the following investigations was to elucidate the constitution of highly polymerised substances and to explain their specific properties. Therefore, the very simple high-polymeric substances have been used, which offered the greatest chance of finding out the apparently so complicated relations between structure and colloidal properties.

<sup>6</sup> Stobbe and Posnjak, *Annalen*, 1910, 311, 292.

<sup>7</sup> As to poly-cyclopentadiene see H. Staudinger and H. A. Bruson, *Annalen*, 1926, 447, 110; as to poly-dimethyl ketene, H. Staudinger, *Helv. chim. acta*, 1925, 8, 306.

<sup>8</sup> See H. Staudinger, *J. R. J. Transactions*, 1935, 10, No. 3.

<sup>9</sup> H. Staudinger, *Trans. Faraday Soc.*, 1933, 29, 18; *Naturw.*, 1934, p. 797.

Furthermore, we selected such synthetic polymers whose colloidal properties were closely related to those of high-molecular natural products. We have therefore especially investigated the polystyrenes,<sup>9</sup> in which the swelling resembles that of rubber and which give also highly viscous solutions. Polystyrenes are saturated hydrocarbons and on account of their greater stability can therefore be more favourably examined than the unsaturated caoutchouc. By polymerising vinyl acetate we obtained high-polymeric esters of which the colloidal properties were very near to those of the cellulose acetates.

One of our principal interests was to learn how the properties of the different monomeric substances are reflected in the properties of organic types of high polymers. We know, for instance, that in the low-molecular state there is a substantial difference between the properties of the homœopolar compounds—for instance hydrocarbons, ethers and esters—and those of the heteropolar substances, such as the salts of organic acids and bases. Furthermore the chemical and physical properties of homœopolar compounds are characteristically changed by certain substituents—the introduction of a hydroxyl group for instance renders insoluble volatile compounds water-soluble and non-volatile.

For this purpose we investigated in addition to homœopolar high-molecular substances (hydrocarbons, ethers, esters), which are soluble in organic solvents, also heteropolar high molecular polymers. Readily prepared representatives of this class are the polymers of the acrylic acid. The heteropolar molecular colloids, such as sodium-polyacrylate are soluble in water and have colloidal properties essentially different from those of the homœopolar polymers—for instance polystyrene or polyvinyl-acetate. Their investigation has revealed much which proved to be important for the understanding of the colloidal properties of solutions of cellulose xanthogenate, of cellulose in Schweizers solution and also of proteins—which are all heteropolar molecular colloids too.

Synthetic high polymers with hydroxyl groups are represented by the polyvinyl-alcohols, obtained by saponification of polyvinyl-esters. These products can be considered as prototypes of starch.

#### IV. Hemicolloids, Mesocolloids, Eucolloids.

The polymerisation of these simple unsaturated compounds to high-polymers is based on the chemical combination of a great number of unsaturated basic molecules (in German: "Grundmoleküle") to a long thread-shaped "macro-molecule." The number of basic molecules or repeating units contained in a single thread depends on the nature of the substance and the conditions of polymerisation. A polymeric molecule can be formed out of 2, or 100, or 1000 basic molecules. The highest known synthetic polymers are built up from 5 to 10,000 molecules.

One and the same initial substance, for instance styrene, vinyl acetate or acrylic ester—can be induced by variation of conditions, *e.g.*, temperature or nature of catalyst, to form polymers with different chain-lengths, although constructed according to the same principle. We call these products of identical structure, differing only in the length of the chain-molecules, a "polymeric-homologous series."<sup>10</sup> Since the physical properties of high polymers change with the length of the macro-molecules, it is possible to prepare, from one and the same initial substance, by changing the conditions of polymerisation, high polymers with very different physical properties. This fact is of great technical importance. One can discriminate between three main groups of molecular colloids, corresponding to different lengths of the fibre-molecules.<sup>11</sup>

**1. Hemicolloids.**—We give this name to polymers with a molecular weight up to 10,000, corresponding to an order of polymerisation, equal to 20 to 100. Their chain-molecules have a length from 50 up to about 250 Å. With such relatively short molecular threads the colloidal properties are not yet very pronounced. The hemicolloids dissolve without swelling, their solutions have a low viscosity, and obey the Hagen-Poiseuille law. The solids are powdery or gluey masses; filaments or films prepared from them have little tensile strength and are easily broken.

**2. Mesocolloids.**—The order of polymerisation of these fibre-molecules ranges from 100 up to about 1000, their molecules having a length from 250 up to about 2500 Å. Their properties are intermediate between those of the hemicolloids and of the eucolloids.

**3. Eucolloids.**—These substances have macro-molecules with a polymerisation order over 1000, the length of the molecules being over 2500 Å. The longest thread-molecules, which so far have been prepared synthetically, are about  $1\mu$  long. The eucolloids have the characteristic properties of lyophilic colloids. Their dissolution is accompanied by an intense swelling, and their solutions are highly viscous, even at low concentrations; they do not obey Einstein's law, and their flow-phenomena are not those of a normal liquid. The solid eucolloidal substances are very tough and hard. The technically most important polymers belong to this group. They show a high capacity for film-formation, and are often highly elastic.

If eucolloids are subjected to an appropriate treatment—for instance a thermal cracking-process or a decomposition by oxidation—products

<sup>10</sup> H. Staudinger, *Angewandte Chem.*, 1929, **42**, 69.

<sup>11</sup> The classification of colloids was discussed in my lecture before the International Congress of Chemistry, in Madrid, 1934. See further, *Ber.*, 1926, **59**, 3019; 1929, **62**, 2893; and a forthcoming communication (No. 117) in the same periodical (*Ber.*, 1935, **68**, 1582).

with shorter molecules can be obtained, having mesocolloidal or hemicolloidal properties. The synthetic hemicolloids—for instance hemicolloidal polystyrenes or polyvinyl acetates—are thus obtainable either by direct polymerisation of the monomeric substances under suitable conditions, or by partial decomposition of the eu colloids. On the other hand natural hemicolloids and mesocolloids can only be obtained by partial decomposition of the natural eu colloids—cellulose or its derivatives. This time no alternative way of getting the same products by synthesis is available.

Whereas some unsaturated compounds—styrene, acrylic ester, vinylacetate—can give hemi-, meso- or eu colloidal products, according to the special conditions of polymerisation, some other compounds have so far yielded hemicolloidal products only. Indene, cumarone, anethole are substances of this kind, giving polymers with relatively short chain-molecules only.

The exact knowledge of the polymerisation process, and especially of the polymerisation order, is very important from the technical point

$\text{CH}_2=\text{O}$	Spontaneous; catalytic.	Insoluble; hardly soluble.	Eucoll. and hemicoll.	20-100	<i>Helv. Chim. acta</i> , 1925, <b>8</b> , 41; <i>Annal.</i> , 1929, <b>474</b> , 145; <i>Book</i> , p. 224.

\* Often only limited swelling polymers are formed; vide H. Staudinger and W. Heuer, *Ber.*, 1934, **67**, 1171.

of view: the hemicolloids and the euolloids having different physical properties, their technical uses are quite different too. For preparing varnishes, for instance, chiefly hemicolloids are used, because the high viscosity of euolloidal solutions is undesirable for this purpose. For artificial resins, from which great tensile strength is highly desirable euolloids are the most suitable materials.

Table IV. gives a list of the simple synthetic high polymers which have so far been investigated in our laboratories in Freiburg, together with their most important physical properties.

We see from Table IV. that high polymers with most different colloidal properties can be obtained synthetically. The number of synthetic substances of this kind has been further increased in recent years, since it was found possible to obtain "mixed" polymers by polymerising mixtures of different unsaturated substances. It is interesting that unsaturated compounds, such as maleic anhydride, which do not polymerise by themselves, form high-polymeric products, when mixed with polymerisable substances, for instance with styrene.<sup>12</sup> These mixed products are of great technical interest; but we do not intend to discuss them further here, because their complicated structure makes them less suitable for the investigation of the relations between colloidal phenomena and molecular structure.

## V. The Process of Polymerisation.

The transformation of unsaturated monomeric substances into polymers can take place in different ways. One is characterised by the conservation of the atomic arrangement of the monomeric substance—as, for instance, in the cases of formaldehyde transformed into trioxymethylene, tetraoxymethylene, or the polyoxymethylenes. Another way is the linking together of two molecules after the shifting of a hydrogen atom, *e.g.*, the transformation of acetaldehyde into aldol, of formaldehyde into sugar or of styrene into distyrene. We call the first reactions *true polymerisations*, these of the second kind *condensation-polymerisations*.<sup>13</sup>

The question: how do the high-polymeric products arise has been answered differently. Some investigators<sup>14</sup> conceived that an unsaturated molecule can form a link with another molecule when a hydrogen atom shifts along the chain. The same process is repeated many times, until the high-polymeric chain is formed. The formation of polystyrenes, according to this theory, occurs in the following way:

<sup>12</sup> Wagner-Jauregg, *Ber.*, 1930, **62**, 3213; Mixed polymers became recently an object of manifold technical interest; the latest patents are reviewed by E. Sauter, *Kolloid Z.*, 1935, **71**, 357. Mixed polymers formed by  $\text{SO}_2$  with unsaturated compounds are described by H. Staudinger and B. Ritzenthaler, *Ber.*, 1935, **68**, 455; Peroxides as mixed polymers, *see* H. Staudinger, *Ber.*, 1925, **58**, 1075.

<sup>13</sup> H. Staudinger, *Ber.*, 1920, **53**, 1081.

<sup>14</sup> G. S. Whitby and J. R. Katz, *J. Amer. Chem. Soc.*, 1928, **50**, 1160; *see also* W. Gallay, *Kolloid Z.*, 1931, **57**, 2.

This theory implies that the formation of the high-polymeric products occurs in steps, each corresponding to a specific compound capable of isolation, as such. In fact, processes of this kind occur, but they lead to relatively low-molecular products and never to high polymers.<sup>15</sup>

The formation of real high polymers must be explained in another way; a molecule of the monomeric substance becomes activated—by heat, light or by a catalyst—and can therefore react with a second molecule. The newly-formed molecule has an "active point" on each its ends, and the polymerisation process can thus proceed further, until an unknown side-reaction makes the active centres disappear. The following scheme describes this process:

The intermediate stages of the polymerisation are in this scheme unsaturated radicals, highly reactive, and therefore incapable of isolation. The reaction has thus the features of a *chain reaction*,<sup>16</sup> comparable with the well-known chain-reactions of low-molecular substances. Only by such a mechanism can extremely high-molecular products of a eucolloid nature be formed synthetically; it could not be done by a process of the kind described by the first scheme.

The assumption that the polymerisation is a chain-reaction is confirmed by the following facts: From the very beginning of the polymerisation-process high-molecular products are already present in the reacting system; the intermediary products which one would expect to occur according to the first scheme, have not been isolated. One can easily prove these statements, *e.g.*, in the case of polyacrylic acid, which is insoluble in the monomeric acid. If we analyse the first small amounts of the polymeric product which are precipitated from the polymerising liquid, we find them to be already very high-molecular. The liquid still consists of pure monomeric acid, without any traces of an intermediate product.<sup>17</sup>

When styrene is polymerised, it changes slowly, first into a highly viscous solution, later into a solid gel. Finally, solid glassy polystyrene is formed from the gel. No stable intermediate products with shorter chains are formed in the course of the polymerisation: the chain-reaction from the very beginning yields high-molecular polymers with a chain-length equal to that of the final product. W. Frost<sup>18</sup> demonstrated this some time ago. He separated from time to time polymerised

<sup>15</sup> H. Staudinger and A. Steinhöfer, *Annalen*, 1935, **517**, 41, showed that distyrene and tristyrene cannot add further molecules of styrene to form polystyrenes.

<sup>16</sup> H. Staudinger and H. W. Kohlschütter, *Ber.*, 1931, **64**, 2093; also *Book*, pp. 149, 223, 255, 289.

<sup>17</sup> H. Staudinger and H. W. Kohlschütter, *Ber.*, 1931, **64**, 2093.

<sup>18</sup> These experiments were made by W. Frost in Freiburg in 1929; they have now been published (*Ber.*, 1935, **68**, 2351).

styrene from the reacting mass, by addition of alcohol, and determined the amount and the order of polymerisation of the product. Table V. shows that the viscosity of a 1 per cent. solution of the polymerised styrene remains nearly the same from the beginning to the end of the polymerisation process, a proof that completely polymerised products are formed already in the first stages of the process.

The polymerisation of styrene differs from that of acrylic acid only because the polymer is soluble in the monomeric substance, whereas the polymeric acrylic acid at once precipitates from the monomeric acid.<sup>19</sup> This is why the polymerisation of styrene at first gives a highly viscous liquid. In this intermediate stage of the polymerisation, the macro-molecules of the polystyrene are dissolved in the monomeric styrene. The properties of such a "gel"-solution are identical with those of the solution of polystyrenes in other organic solvents, *e.g.*, in benzene. The polymeric molecules, which are contained in liquid styrene, have the same length as those contained in the final product of the polymerisation, the solid polystyrene-glass.

High-molecular polymers can be obtained also in other ways. Carothers<sup>20</sup> showed, for instance, that they are obtainable by "polycondensation" of poly-basic acids with glycols. Polycondensations do not yield, however, eucolloidal products, like the chain-polymerisations of unsaturated compounds, because with growing length of the macro-molecule the chances for a further condensation-reaction become smaller and smaller. That is why so far only products with a molecular weight up to 20,000-30,000 have been prepared by polycondensation, whereas by chain-reactions, as mentioned above, products with a molecular weight up to 500,000 and more may be obtained.

## VI. Constitution of the Synthetic High Molecular Products.

When high-polymeric substances were first investigated there was much discussion as to whether these substances are built up from *macromolecules*,<sup>21</sup> or from *micelles*.<sup>22</sup> Without referring much to this discussion, we may mention that the macromolecular structure of high-

molecular substances was first definitely proved by the experiments on poly-oxymethylenes.<sup>23</sup>

The principal question to be answered in the case of a high-polymer giving a colloidal solution is : are the dissolved particles micelles, as first supposed, or are they identical with the macro-molecules of the polymer ? The essential property by which a macro-molecule differs from a micelle is that, in a macro-molecule, all the atoms are linked together by normal co-valent links, as in ordinary organic molecules. The only difference between macro-molecular and low-molecular substances is that, whereas the latter consist of absolutely identical molecules, the former are built up of a mixture of polymeric homologous molecules. Because of the resemblance between the physical properties of all these molecules, it appears impossible to separate the polymerised substance into its single chemically pure components.<sup>24</sup> A *micelle*, on the other hand, is a particle built up from small single molecules held together by van der Waals' attraction forces.<sup>25</sup>

It was thus necessary to investigate the source of the colloidal properties of the solutions of high-molecular substances, e.g., their high viscosity and their swelling capacity. Are these properties due to a micellar structure, or are they to be explained by the great size of the molecules ? It is a very important question, because the colloidal properties of many solutions of macro-molecular substances (e.g., of rubber, in benzene, or of sodium acrylate in water), are similar to those of some undoubtedly micellar solutions, e.g., of soaps. Both kinds of solution are highly-viscous, and do not obey the law of Hagen and Poiseuille. The dissolution of both is accompanied by a strong swelling. Important differences exist, however, for instance, in the hardness and tensile strength of the solid substances and in the stability of the solutions.

The resemblance in the colloidal properties of the different kinds of solutions must be ascribed to the fact that all contain dissolved particles in the shape of long threads. The differences are explained by the assumption, that these particles are *thread-micelles* in the case of soaps, but *thread-molecules* in the case of rubber, and polyvalent *thread-ions* in the case of sodium polyacrylate. An understanding of the whole of the properties of these colloids can be obtained only by elucidation of the constitution of their colloid particles.

*The macro-molecular structure of the colloid particles of high-molecular substances has been proved in the same way as that by which the structure of ordinary low-molecular organic substances is usually investigated.* By changing the conditions of polymerisation it was possible to obtain, from one and the same initial unsaturated monomeric substance, a whole *polymeric series* of different polymerisation-products. In studying a series of this sort, one finds that the physical properties (of the solid products as well as of their solutions) change gradually with growing length of the molecule. The relations between physical properties and chain-length are

<sup>23</sup> H. Staudinger and U. Fütty, *Helv. Chim. Acta*, 1925, 8, 41; also H. Staudinger and R. Signer and others, *Annalen*, 1929, 474, 145.

<sup>24</sup> As to macro-molecules see H. Staudinger and J. Fritsch, *Helv. Chim. Acta* 1922, 5, 785; *Book*, p. 5.

<sup>25</sup> A certain confusion in the field of polymers was caused by an identification between the "micelles" as defined by Nägeli—i.e., small crystallites in the organised fibres, e.g., of cellulose—and the colloid particles in solutions. This identification was repeatedly tried—for instance by R. O. Herzog (*Ber.*, 1925, 58, 1254; *J. Physic. Chem.*, 1926, 30, 457, who assumed that the micelles (crystallites) in cellulose-fibres are of the same size as the micelles (colloid particles) in the colloid solution of cellulose; see discussion of this point in *Book*, p. 31.

of the same kind as those known to be valid in the homologous series of ordinary organic compounds. We may conclude from this that the whole polymeric series, beginning with the hemicolloids and ending with the eucolloids, is built up in the same manner, and differs only in chain-length.

Another proof of the macromolecular structure of high polymers is furnished by the analytical determination of the *end-group* of the thread molecules. But as in the ordinary homologous series, the relative amount of matter belonging to the end-groups of the macro-molecule decreases with its increasing length. Since the length of the macro-molecule is generally very great, this amount is always small; the analytical determination of the end-groups is therefore possible only in some especially favourable cases, and the results are rather inaccurate. Nevertheless with some polymeric series of especially simple structure, it was possible to prove that the relation between the mass of the end-groups and the mass of the whole molecule decreases, conforming with calculations, with increasing order of polymerisation. The substances with which this proof was possible were the poly-oxymethylene dimethyl ethers,<sup>26</sup> the poly-oxymethylene diacetates,<sup>27</sup> and the poly-ethylene-oxide-diactates;<sup>28</sup> the end-groups in question were thus the acetyl and the methoxyl group. This method is of course not appropriate for use with very high-molecular eucolloidal products, with a molecular weight of 100,000 and more. It is for instance impossible to determine the molecular weight of cellulose or of caoutchouc by this method.<sup>29</sup>

The most important proof for the macro-molecular structure of high polymers is their transformation into polymeric-analogous derivatives, that is, into polymers with the same order of polymerisation, but with different substituents. Of course, only substitutions which can be carried out at low temperatures, without unduly affecting the unstabler macro-molecule, can be used for this purpose. The "skeleton" of the macro-molecule is much more sensitive and unstable than that of the ordinary molecules, and the carbon links are the more readily cracked, either by heat or by oxydation, the higher the weight of the molecule.<sup>30</sup> This leaves relatively few possibilities of substitutions, at least so far as the relatively stable synthetic high-molecular products are concerned. As an example of substitutions of this kind we may quote the gently catalysed reduction of hemicolloidal polystyrenes, which leads to the polymeric-analogous hydro-polystyrenes of the same order of polymerisation.<sup>31</sup>

<sup>28</sup> H. Staudinger and H. Lohmann, *Book*, p. 298.

<sup>29</sup> The end-groups of partially degraded derivatives of cellulose have been determined by W. N. Haworth and H. Machemer, *J. Chem. Soc.*, **132**, 2270; see in this connection H. Staudinger, *Annalen*, 1933, **501**, 170.

<sup>30</sup> As to the tearing of thread molecules of polystyrene, see H. Staudinger and W. Heuer, *Ber.*, 1934, **67**, 1159.

<sup>31</sup> *Ber.*, 1926, **59**, 3033; also H. Staudinger and V. Wiedersheim, *Ber.*, 1928, **62**, 2406.

A much greater variety of possible transformations of this kind can be realised with high-molecular natural products, which are more reactive than the corresponding synthetic substances. It is for instance possible to convert caoutchouc, with a molecular weight of 64,000, composed of 1000 isoprene radicals, into a hydrocaoutchouc with the same length of the molecules.<sup>32</sup> This reduction is represented by the formula:

In an analogous way, cellulose can be transformed into polymeric-analogous acetates<sup>33</sup> or nitrates<sup>34</sup> without breaking the long chains. The cellulose acetates can be converted back into polymeric-analogous cellulose by saponification;<sup>35</sup> or they can be transformed into methyl cellulose<sup>36</sup> again without changing the order of polymerisation. It is thus possible to carry out the same transformations with high-molecular substances as with ordinary low-molecular ones; the macro-molecular structure of high polymers is definitely proved in this way.

### VII. Determination of the Molecular Weight of High Polymeric Substances.

Since the most important physical properties of the high polymers—their hardness, swelling capacity and the colloidal behaviour of their solutions—depend on the length of their chain-molecules, it becomes very important to determine this length as exactly as possible.

The ordinary cryoscopic or ebullioscopic methods of determination of molecular weight can only be used with hemicolloids (molecular weight up to 10,000), but not with meso- or eucolloids, the corresponding effects being too small in these latter cases. It was, however, possible to use the osmotic method, even in the case of eucolloids, particularly developed by G. V. Schultz in Freiburg; the abnormal osmotic phenomena, which formerly prevented exact investigations of this kind, are now better understood and kept under control.<sup>37</sup>

Another reliable method for determining particle weights is the ultra-centrifuge, as used by Svedberg. So far it has been used chiefly for determining the molecular weight of proteins.<sup>38</sup> Signer and Gross<sup>39</sup> used it recently for molecular-weight-determinations of synthetic high polymers, especially those of polystyrene. However, this method is too expensive and complicated to come into general use.

A simple method for calculating the molecular weight (or the chain-length) of high-molecular substances is that based on the measurement of viscosities. It is especially convenient for comparing the different members of a polymeric homologous series.<sup>40</sup> Experiments of this kind contributed much to the understanding of the constitution of high polymeric substances. Measurements of the specific viscosity of their

<sup>38</sup> Svedberg and Lewis, *Amer. Chem. Soc.*, 1928, **50**, 25; and subsequent papers; see e.g. *Kolloid-Z.*, 1930, **51**, 10.

<sup>39</sup> See R. Signer and H. Gross, *Helv. Chim. Acta*, 1934, **17**, 59, 335, 720.

<sup>40</sup> H. Staudinger and W. Heuer, *Ber.*, 1930, **63**, 222.

solutions under different conditions (variable concentration, variable temperature, different solvents) give valuable hints as to the nature of the colloidal particles involved—especially their micellar or macro-molecular structure.<sup>41</sup> If the macro-molecular structure is established by chemical investigations (as described in the previous section), and the shape of the molecules is known to be thread-like, very simple relations hold between the specific viscosity (at least so far as low-viscous solutions are alone concerned) and the length of the macro-molecules (formula I) or the molecular weight (formula II).<sup>42</sup>

$$\eta_{sp} (1.4 \text{ per cent.}) = \gamma \times n \quad . \quad . \quad . \quad (I)$$

$$\eta_{sp} (\text{gd. mol.}) = k_m \times M \quad . \quad . \quad . \quad (II)$$

Formula (I) refers to the specific viscosity of the solutions of thread-shaped molecules of constant concentration (1.4 per cent.). It shows this viscosity to be proportional to the number of chain-atoms  $n$ . The coefficient  $\gamma$  represents the viscosity-equivalent of a carbon—(or oxygen)—atom in 1.4 per cent. solution. This formula holds for simple thread molecules only, i.e., molecules without rings in the chains. With molecules containing rings, there are some complications, but it still remains possible to calculate  $n$ .<sup>43</sup>

The second formula is obtained by a simple transformation of the first.<sup>44</sup> It makes possible the direct calculation of the molecular weight  $M$  from the specific viscosity of  $\eta_{sp}$  (gd. mol.) of a solution containing one mol. of the monomeric substance (the repeating unit) per litre—provided that the constant  $K_m$  is known for the homologous series in question. The validity of these viscosity formulæ has been proved not only on a great number of low-molecular chemical compounds with thread-shaped molecules, but also on a great number of hemicolloids.<sup>45</sup>

The only question is whether these relations hold also for extremely high-molecular substances of eucolloidal character and can be used for calculating the molecular weight of substances of this kind? Since the flow-phenomena in solutions of eucolloids are not normal, it seems doubtful whether viscosity-data can be used for the calculation of molecular weights. But in low-viscous solutions, which alone are used for the determination of the molecular weight, the deviations from the law of Hagen-Poiseuille are so small, that the calculations of  $\eta_{sp}$  (1.4 per cent.) or of  $\eta_{sp}$  (gd. mol.) from the actual measurements of viscosity are not too uncertain.<sup>46</sup>

The usefulness of the viscosity-method for the determination of molecular weight of eucolloids is shown by the fact that, using the results of previous osmotic determinations for cellulose acetates and nitrates,<sup>47</sup> and combining them with viscosity data we got a value of about  $10 \times 10^{-4}$  for the constant  $K_m$ —i.e., the same value as obtained by investigations of the hemicolloids.<sup>48</sup> The same value was calculated from the viscosities

<sup>41</sup> See Book, p. 96.

of the acetates of cellotetraose<sup>49</sup> and cellopentaose<sup>50</sup> prepared by Zechmeister<sup>51</sup>—i.e., from well-defined homogeneous compounds. In Freiburg, G. V. Schultz investigated a series of nitrocelluloses and methyl-celluloses and found, that using the value  $K_m = 10 \times 10^{-4}$  one obtains values for the molecular weight which are in complete accordance with those calculated by the osmotic method (see Table VII.).

TABLE VII.—COMPARISON BETWEEN THE MOLECULAR WEIGHTS OBTAINED FROM MEASUREMENTS OF VISCOSITY AND OF OSMOTIC PRESSURE.

Substance	$\lim \frac{\eta}{c} \times 10^3$	$M$ (Osmot.)	$\lim \frac{\eta_{sp}}{c}$ g. d.m.	$M$ (Viscos.) with $K_m \times 10^{-4}$	$K_m \times 10^{-4}$ Found

Degradation product	0.62	39,300	5.05	28,000	1.29

The validity of the viscosity-law given above is thus demonstrated in a rather wide region, at least for natural high-molecular products, caoutchouc and cellulose.

In the case of synthetic high-polymeric substances, however, the molecular weights obtained by measurement of viscosity often differ from those determined osmotically. In the case of poly-ethylene-oxides G. V. Schultz proved the "viscosimetric" molecular weights to be somewhat lower than those calculated from osmotic experiments. The deviations are, however, not very considerable (see Table VII.).

With polystyrenes, the discrepancies become much larger: the molecular weights determined osmotically are two, three or four times higher than those calculated from viscosity-data (Table VIII.).

The values obtained from *osmotic measurements* are roughly in agreement with those found by R. Signer and H. Gross<sup>52</sup> with the *ultra centrifuge*.

200	I	157,000	6.55	36,500	0.415	0.415

In calculating  $M$  from viscosity-data, a value  $K_m = 1.8 \times 10^{-4}$  was used, obtained from viscosities of substances whose molecular weight could be measured cryoscopically.<sup>53</sup> This experimental value is in good accordance with that obtained from viscosity-measurements on low-molecular compounds of known structure,<sup>54</sup> which is  $1.86 \times 10^{-4}$ .

The discrepancy between the "osmotic" and the "viscosimetric" values of the molecular weight does not indicate the inexactitude of the viscosity-law in the case of high-molecular polystyrenes. This law is known to be valid in the case of cellulose-derivatives, which are very high-molecular. It is necessary to assume that the synthetic high polymers, produced by chain-reactions, are composed not of simple thread-molecules, but either of high-molecular rings, or of branched chains, formed by some unknown side-reactions. These side-reactions become stronger with rising temperature of polymerisation.

This is the cause of the greater discrepancy between osmotic and viscosimetric determinations of molecular weights in the case of mesocolloidal polystyrenes, obtained by polymerisation at 200°, as compared with higher-molecular euocolloidal products, which are formed at lower temperatures. The discrepancy has nothing to do with an alleged invalidity of the viscosity-laws at higher chain-lengths; otherwise the deviations would be highest in the case of euocolloidal substances, which have the longest molecules. It is, of course, very difficult to prove more

directly the existence of branching chains by investigation of the polymerised substances. In a second paper presented to this meeting, we shall demonstrate the strong influence of small amounts of certain foreign bodies upon the straight chain-structure and the properties of high-polymeric substances.<sup>55</sup>

We are led to the following conclusion: whereas osmotic measurements permit the calculation of true molecular weights, viscosity-data give correct results concerning the chain-length. We must bear in mind, however, that the chain-length, and not the molecular weight, is the most important thing from the point of view of the colloidal properties of high-molecular substances.

### VIII. Relation between the Physical (Colloidal) Properties of High Polymeric Substances and the Chain-Length of their Molecules.

The most important result of the foregoing discussion can be re-stated as follows: the differences in the colloidal behaviour of high-polymeric substances are based on differences in the lengths of their macro-molecules—and not on different micellar structure, as was hitherto supposed. Synthetic and natural high-polymers with a given chain-length show a characteristic behaviour, irrespective of their molecular structure (for instance, their saturated or unsaturated character). Hydrocarbons, ethers, esters all have the same colloidal properties, so long as their order of polymerisation is the same; the essential colloidal phenomena, especially those of the viscosity of the solutions are mainly dependent on the lengths of the macro-molecules and to some extent on the solvation<sup>56</sup> and wholly independent on the special chemical structure. The only condition is the purely homœopolar nature of the compound.

It is a well-known fact that many physical properties of low-molecular compounds are primarily functions of their molecular size, e.g., osmotic pressure and volatility. All homœopolar organic compounds with a molecular weight of about 100 are liquids, with about the same boiling-points—whether saturated or unsaturated substances, hydrocarbons, ethers or esters; furthermore they have the same osmotic pressures (when dissolved in the same solvent). Homœopolar organic substances with a molecular weight of about 500 are all much less volatile and possess also about the same boiling-points.

The same connection between molecular size and properties exists also in the range of macro-molecules. Aliphatic hemicolloids with about 200 chain-atoms all have the same appearance—independent of whether they are hemi-colloidal hydrocarbons, or partially degraded hydrocaoutchoucs, or caoutchoucs or poly-isobutylenes, or esters such as polyacrylic-ester, polyvinyl-acetates. They are all solids, either glue-like or powdery, dissolving without swelling and giving low-viscous solutions. Their specific viscosity in 1.4 per cent. solution is about 0.26 to 0.3 (dependent on the nature of the solvent). Eucolloidal products—caoutchoucs and hydrocaoutchoucs, poly-isobutylenes, polyacrylic esters, etc., with about 5000 chain-atoms, are all tough elastic solids, which swell strongly and form highly viscous solutions. The viscosities of these solutions are about the same for all of these products (so long as solutions in the same solvent and with equal concentrations are compared).

<sup>55</sup> See the second paper: "The Soluble and Insoluble Polystyrenes."

<sup>56</sup> H. Staudinger and W. Heuer, *Z. physik. Chemie (A)*, 1934, 171, 129.

The properties of heteropolar substances are essentially different—with low molecular substances as well as high polymers: the properties of sodium acetate are quite different from those of ethyl acetate, although their molecular weights are not very different. In the same way, *the colloidal properties of sodium polyacrylate differ strongly from those of an ester of the polyacrylic acid, even when both have the same chain-length.*

The viscosity of the solutions of heteropolar molecular colloids depends not only on the length of the molecular chains, but also to a high degree on the *formation of swarms between the fibre-ions*. That is why solutions of sodium polyacrylate are much more viscous than those of polymeric-analogous polyacrylic esters with the same chain-length. Due to the formation of swarms, solutions of mesocolloidal heteropolar polymers show deviations from the Hagen-Poiseuille's law, whereas in the case of homœopolar molecular colloids deviations of this kind occur first at a much higher order of polymerisation. Addition of an electrolyte disturbs the electrolytic forces which are responsible for the formation of swarms. The solutions of hetero-polar molecular colloids have therefore different viscosities at different concentrations of electrolytes.<sup>57</sup> By addition of a large amount of electrolyte, the formation of swarms can be suppressed completely. In this case, the viscosities of heteropolar colloids—for instance of sodium poly-acrylate—obey the same relations which are valid for homœopolar polymers. Under these conditions, the viscosity depends only on the length of the chain-ions and on their solvation. This discovery has contributed much towards the understanding of the structure of heteropolar molecular colloids.<sup>58</sup>

### IX. Classification of Colloids, Based on the Structure of High-Molecular Polymers.

It is well known that the characteristic differences between the behaviour of a solution of glue and that of ordinary solutions of low-molecular substances brought Graham to the notion of a special state of dissolved matter known as the colloidal state. The number of colloidal substances now known is very large, and between them great differences in properties can be observed. These differences lead to a discrimination between two chief classes of colloids: the *lyophilic* and the *lyophobic* colloids.<sup>59</sup> This classification is based on the assumption that the swelling of certain solid substances which give colloid solutions, and the high viscosity of these solutions, are based on an especially strong solvation of the colloid particles in question. Other authors prefer to discriminate between *suspensoids* (grain-colloids) and *emulsoids* (drop-colloids), assuming a different state of aggregation of the colloid particles in these two cases. The high-molecular substances belong to lyophilic colloids according to the first, or to the emulsoids according to the second classification. Nowadays, since investigation of the structure and size of the colloid particles of high-molecular substances has led to definite results, a further classification of the colloids appears reasonable.<sup>60</sup>

Neglecting the inorganic colloids, whose structure may be very different, we can divide all organic colloids into two classes: the *micellar* and the *molecular* colloids.

<sup>57</sup> H. Staudinger and E. Trommsdorff, *Book*, p. 333.

<sup>58</sup> H. Staudinger and E. Trommsdorff, *Annalen*, 1933, **502**, 201.

<sup>59</sup> H. Freundlich, " *Kapillarchemie*," 4th edition, Vol. II., pp. 2 and 3 (1932).

<sup>60</sup> As to the classification of colloids, see *Ber.*, 1935, **68**, 1682.

We have shown in this paper, how differences in the shapes of the colloidal particles affect the properties of their solutions. This causes us to distinguish between *sphero-colloids* and *linear colloids* (or *thread-colloids*).<sup>61</sup>

**A. Sphero-Colloids.**—Colloids of this kind can never produce solutions of high viscosity, since from Einstein's formula:  $\eta_{sp} = 2.5\phi$  we calculate that a solution containing 1 volume in 100 of spherical colloidal particles must have a viscosity of not more than 0.025. This value is to be compared with the high viscosities (up to  $\eta_{sp} = 10$ , or even 100), which are actually shown by 1 per cent solutions of many lyophilic colloids. The solutions of the sphero-colloids obey the Hagen-Poiseuille law. No swelling occurs during their dissolution.

**B. Linear Colloids.**—These colloids produce highly-viscous solutions, because the viscosity of a solution containing long, fibre-shaped particles depends on the size of the fibres (whereas in the case of spherical colloids the viscosity is independent of the size of the particles). At a given concentration, the viscosity increases strongly with increasing length of the colloidal particles. This applies to the micellar colloids (e.g., soaps), as well as those with fibre-shaped macro-molecules, and their solutions.

The high viscosity of the solutions of rod-shaped particles can be explained by assuming a great size of their "spheres of action." It is therefore possible to prepare a solution of linear particles in which each particle is completely solvated—and still remains in interaction with the neighbouring molecules (or micelles).<sup>62</sup> The viscosity of gel-solutions<sup>63</sup> of this kind may attain extremely high values—some high-molecular substances give solutions with viscosities a 100 times greater than that of the pure solvent. *This is characteristic for linear colloids; it would never occur with sphero-colloids.*

Solutions of linear colloids show deviations from the Hagen and Poiseuille law, which become greater with growing length of the particles.<sup>64</sup> Solid linear colloids are dissolved with strong swelling, which becomes especially intense with the longer particles.<sup>65</sup>

The difference in the colloidal behaviour of the two classes can be further demonstrated by the following example. By polymerising unsaturated compounds—for instance, styrene—in a solution of soap, it is possible nowadays to prepare an artificial latex, whose internal structure does not greatly differ from that of the natural product.<sup>66</sup> The polystyrene-latex and natural latex both contain spherical particles. By changing the conditions, it is possible to obtain particles of different size, and polystyrenes with a different order of polymerisation.<sup>67</sup>

<sup>61</sup> Molecular colloids may be sphero-colloids, but are usually linear colloids. Molecular colloids, with spherical particles, have been so far observed with proteins only; Svedberg and N. Lewis, *J. Amer. Chem. Soc.*, 1928, **50**, 525, and subsequent papers; G. Boehm and R. Signer, *Helv. chim. acta*, 1931, **14**, 1370. A synthetic preparation of a spherical colloid remains yet to be achieved; by polymerisation of unsaturated compounds so far only linear colloids have been obtained.

<sup>67</sup> See the forthcoming paper by H. Staudinger and E. Husemann, *Ber.*, 1935, **68**, 1631.

The emulsions of latex are sphero-colloidal solutions, having, therefore, a low specific viscosity (0.025 at a concentration of 1 per cent.), independent of the size of the latex-drops and of the macromolecules of polystyrene from which these drops are built up. These results are confirmed by the investigations of Bancelin<sup>68</sup> on rubber suspensions.

The polystyrene can be precipitated from the synthetic latex by the same substances which precipitate rubber from rubber-latex, e.g., acetic acid or acetone. By dis-

solving the precipitated polystyrene in benzene, we obtain highly viscous solutions of a linear-colloidal type. Table X. gives a comparison between the viscosities of a

1 per cent. solution of polystyrene-latex and a polystyrene-solution of the same concentration. The relation is sometimes as high as 1000; it is seen that the viscosities of the polystyrene solutions change strongly with the length of the molecules.

### GENERAL DISCUSSION.

**Dr. R. Houwink** (*Eindhoven*) said: I suggest that the view that polycondensations do not yield eucolloidal products must be restricted to linear polymers. 1 or three-dimensional polymers the phenol-formaldehyde resins are a proof of the contrary. I would like to know how the low viscosity of a polystyrene latex can be brought into accordance with the rigidity of the polystyrene chain molecules, which has often been defended by Professor Staudinger.

**Professor K. H. Meyer** (*Genève*) said: Dr. Staudinger says, in Chapter VI. of his paper, that there was much discussion as to whether substances such as cellulose are built up from macromolecules or from micelles. We think that this alternative is not justified. Cellulose is built up from long chains, the length of which was determined (by a Roentgenographical method) by Mark and myself<sup>69</sup> as early as 1928 to correspond to at least 100 glucose residues,<sup>70a</sup> which is in harmony with the

<sup>68</sup> Bancelin, *Comptes rendus*, 1911, **152**, 1382.

<sup>69</sup> *Z. physik. Chem.*, 1928, **2B**, 128.

<sup>70a</sup> The first preliminary value of 30-50 glucose residues, quoted several times by Staudinger, was replaced in 1928 by the value of "at least 100 residues, held together by cellobiose linkages," which resulted from our own measurements. At this time Staudinger's views on the structure of cellulose were still quite undefined; he wrote (*Ann.*, 1929, **474**, 150); *Bei der Cellulose ist die Frage noch offen, ob die einzelnen Moleküle wie Glukose-, bzw. Cellobioseanhydrid-Moleküle durch normale oder durch koordinative Covalenzen gebunden sind.*

recent work of Haworth,<sup>70</sup> who finds 200 rings in a chain. These chains in the natural, and any solid state are clustered together to crystalline aggregates, called micelles. Staudinger's alternative is expressed as if one were to discuss whether a house is built up of bricks or of walls.

Staudinger considers the chemical transformation of high polymeric substances into polymeric analogous substances (e.g., polystyrene into hypopolystyrene of the same particle size) as the most important proof for their macromolecular structure and against the existence of micelles or aggregates in solution. We do not think that this argument is conclusive. Oleic acid is bimolecular in apolar solvents, and forms polymeric micelles in aqueous alkaline solution. If we hydrogenate it, we get stearic acid, which forms double molecules or ionic micelles of about the same particle size as oleic acid. Other acids will give analogous results, and show other characteristic particle sizes. According to Staudinger, this would be a definite proof of the "macromolecular structure," and the absence of micelles in these compounds. But in our opinion real physical (e.g. Roentgens graphical) and chemical arguments exist in favour of very long primary valency-chains (in cellulose, rubber, etc.).<sup>71</sup>

On the other hand, there is, as Haworth has pointed out, and Rideal mentioned in his introductory paper, very much evidence in favour of the assumption that, in solution, the particles of cellulose and other substances with dipoles are composed of several primary valency-chains. The same opinion has been expressed by us, but we have never admitted, as Staudinger seems to interpret our views, that the crystalline micelles of the natural cellulose persist in the same state in the solution. On the contrary, we emphasised that intramicellar swelling precedes the dissolution.

**Professor H. Pringsheim (Paris)** said: I have observed that by heating inulin, even in aqueous solution, can be transformed into a substance which is easily soluble in water. I have called this substance "Inulan" while Dr. Katz prefers to call it "soluble inulin". This substance if left for a certain length of time in a dessicator will change back into the original inulin with the original chemical qualities: the same difficult solubility in water and the same X-ray diagram. I cannot see how this can be explained on the basis of the theories here accepted for the constitution of high-polymer polysaccharides and I would like to ask whether anybody here present could give me an explanation.

**Professor H. I. Waterman (Delft)** said: Does Professor Staudinger not agree that the conclusion: "unsaturated compounds with conjugated double bonds are generally more reactive than those with isolated double bonds" will have many exceptions? It is known from experiments in

the Delft laboratory that the isobutene  $\left[ \begin{array}{c} \text{C} \\ | \\ \text{C} \quad \text{C} \quad \text{C} \end{array} \right]$  polymerisation even at  $-80^{\circ}\text{C}$ ., has an explosive character.

In the reaction "caoutchouc/ $\text{C}_3\text{H}_6/1000 \rightarrow 1000\text{H}_2$  Hydrocaoutchouc/ $\text{C}_3\text{H}_{1000}$ " was it proved that (a) the raw material which is hydrogenated is absolutely free from rings, and (b) there is no cracking or ring formation during the hydrogenation?

<sup>70</sup> *Proc. Address, Sect. Chemistry, Brit. Assoc., 1935.*

<sup>71</sup> It seems to have been forgotten that the macromolecular cellobiose formula of cellulose was proposed long ago with very strong arguments by different authors, e.g., Jacobson in the *Lehrbuch der organischen Chemie* (Meyer-Jakobson, 2nd ed., 1913), who says: *Wir können aus der Gesamtheit der Eigenschaften (der Polysaccharide) schliessen, dass es sich um Körper von sehr hohem Molekulargewicht handelt. . . . In einzelnen Fällen gelingt es, durch gemässigte Hydrolyse Disaccharide abzuspalten (Maltose aus Stärke, Cellobiose aus Cellulose). Man darf dann schliessen, dass die in diesen Disacchariden sich findende Verkettingsart je zweier Monosaccharidereste auch dem molekularen Aufbau des komplexen Polysaccharids zugrunde liegt.*

In my opinion a cracking reaction cannot generally be accepted as a proof of the constitution of styrene polymers. The cracking reaction was indeed proposed by Professor Staudinger during the discussion on de Boer's paper as an argument for a special constitution. I believe that this can give rise to mistakes, unless it is proved in another way that the decomposition in cracking is not combined with side-reactions, *e.g.*, polymerisation.

**Dr. E. Bergmann** (*Rehoboth*) said: (1) One cannot divide the polymerisable substances into two classes: substances polymerising spontaneously and substances polymerised under the influence of catalysts. Indene, *e.g.*, on keeping, polymerises easily, whilst according to Professor Staudinger's statement a catalyst is necessary. If one considers polymerisation as a chain reaction, even on theoretical reasons the above discrimination cannot be maintained, since the chain needs a starter catalyst.

(2) The statement that negative groups, such as phenyl or chlorine, increase the polymerisability of ethylene compounds, applies only for the pair ethylene-styrene, whilst in the case of butadiene-phenylbutadiene the reverse is true. The careful study of the influence of substituents may give, from the chemical side, an insight into the nature of the "steric factor," concerned in the polymerisations, as has been discussed already with regard to previous papers.

(3) Regarding the constitutional regularity of the polymerisation process, a paper by Midgley and Henne may be quoted; they showed that the dimerisation of isoprene with sodium metal in presence of hydrogen gives not only the dimerisation corresponding to natural rubber

but also the following chains:

The conclusion is obvious that if the same applies to the polymerisation process, the regularity necessary for giving an X-ray pattern will not be reached, and that may account for the failure to obtain X-ray diagrams from artificial polyisoprene.

**Professor H. Mark** (*Wien*) said: For everybody who seeks to study the kinetics of polymerisation reactions Table I. of Staudinger's contribution is of the greatest importance. It will be the main task of physical measurements and of calculations, which are based on these measurements, to explain why several substances polymerise with difficulty, whilst other very similar substances polymerise easily. It seems to me that the idea of chain reactions, which has already been pointed out by different authors (as mentioned by Professor Rideal in his introductory paper) and which Dr. Dostal and I have worked out to a certain extent, furnishes a sufficient number of possibilities of explaining the complicated experimental behaviour.

That ethylene does not polymerise may be understood from the fact that the double bond in this molecule is activated only at somewhat high temperatures, at which the chains formed by this activation disintegrate again with a remarkable velocity. This means, that nuclei are only built with appreciable rate at temperatures, which are so high that the resulting product is already unstable. On the other hand, it was found possible to polymerise ethylene together with styrene or vinyl chloride. This is due to the fact that the radicals, which induce the polymerisation of

styrene are sufficiently active to induce also the polymerisation of ethylene. That polymerising substances may induce other substances to polymerise with them has a certain analogy to similar effects in explosions and is characteristic for the occurrence of a chain reaction. The large amount of material contained in the numerous publications of Professor Staudinger furnishes a great number of valuable points of view for the quantitative analysis of polymerisation reactions.

The fact that condensations and especially esterifications mostly lead only to hemicolloid molecules of medium chain-length can very easily be understood from the standpoint of a chain reaction. In these cases the rate of the first step of the polymerisation which leads from  $A_1$  to  $A_2$  is, in regard to its activation energy, identical with every step which leads from  $A_n$  to  $A_{n+1}$ . In all cases one has to deal with the splitting-off of water, by which an ester is built. An activated state or a free radical is not to be taken in account. Therefore one sees no reason why, after a slow chain production, a rapid chain growth should begin. One has simply a reaction of stepwise esterification, which slowly builds up the macromolecules. At the same time new molecules  $A_2$ ,  $A_3$ , etc., are always formed and together with the slowly growing chains to form the monomeric material. The formulae which we have derived in our contribution make it possible to follow this behaviour quantitatively.

**Dr. J. H. de Boer** (*Eindhoven*) said: It may be assumed that some thread-like polymers have a stretched form in some liquids in which they are solvated to a high degree, while the same polymers will have a spiral form in other liquids which are not bound by solvation forces. When a chain has the property of giving a spiral form by the working of the van der Waals' forces along the chain, one may expect this in the first place in the dilute gaseous state. When brought into a liquid, there are two possibilities. Suppose we have a polymer molecule  $A \dots A$  and two molecules of some liquid B, we may distinguish the combinations

in which each A-group has bound a molecule B by van der Waals' forces, and

in which the A-groups attract each other and the molecules B do the same. In case I. we have the van der Waals' binding energy

$$Q_I = 2 \cdot \frac{3}{2} z_A z_B \frac{h\nu_A \nu_B}{\nu_A + \nu_B} \approx \frac{1}{\nu_A},$$

whereas we have in case II:

$$Q_{II} = \frac{3}{2} z_A^2 h\nu_A \approx \frac{1}{\nu_A^2} + \frac{3}{2} z_B^2 h\nu_B \approx \frac{1}{\nu_B^2}.$$

When  $\nu_A = \nu_B$  and  $z_A = z_B$ , so when the dispersion liquid has about the same physical properties as the groups of the polymer,

$$Q_I = Q_{II}.$$

On account of, let us say, steric factors, we may expect that the A-A-attraction is smaller than it would be when the A-groups were entirely free, so

$$Q_I < Q_{II},$$

and there will be a great solvation and a tendency to form stretched molecules in this liquid.

When, however,  $\nu_A \neq \nu_B$  and  $z_A \neq z_B$ , as when the molecules of the liquid have entirely other physical properties than the groups of the polymer, then

$$Q_I < Q_{II},$$

and there may be a tendency to form spirals, and the solvation is small.

This behaviour seems to me to be in accordance with the results of Professor Signer,<sup>72</sup> where he states that there is a large double refraction of flow in the case of polystyrene, dissolved in benzene, toluene or the like, but that in other liquids the double refraction of flow has much smaller values and the molecules of polystyrene have not a stretched form. This latter behaviour may be expected to a higher degree, the greater the difference between the molecules of the liquid and the groups of the polymer.

**Dr. E. W. Fawcett** (Winnington) said: In connection with Professor Staudinger's remarks on the relative ease of polymerisation of various unsaturated compounds, I should like to report some preliminary results on the polymerisation of ethylene under high pressures. The polymerisation of ethylene when carried out at ordinary or moderately high pressures with or without the addition of catalysts, does not usually lead to the production of products of very high molecular weight—the products generally being liquids of molecular weight of the order of 100-500. When, however, ethylene is heated to 170° C. under a pressure of about 1000 atms., a slow polymerisation occurs leading to the production of a white solid polymer. This is insoluble in acetone, and moderately soluble in benzene, has a carbon and hydrogen content corresponding to the formula  $(CH_2)_n$ , and a molecular weight by boiling-point elevation in benzene of about 1000. In spite of the fact that the reaction was by no means complete—only about 10 per cent. of the ethylene had reacted—no liquid products of low molecular weight were produced, and the reaction appears to be quite analogous to the well-known chain polymerisation of styrene and similar substances. When an attempt was made to carry out the reaction at a pressure greater than 1400 atms., a very violent exothermic reaction occurred with the production of carbon, hydrogen and simple hydrocarbons.

**Professor H. Staudinger** (*Leipzig 1. Br.*), in reply, said: I will take these questions together which cover a similar field. In regard to the questions of Waterman, Bergmann, Mark, and Fawcett, it should be pointed out (as H. Mark has already stated), that Table I. of my paper is only of a qualitative nature in order to direct attention to the multiplicity of the phenomena. Naturally, it is very difficult to decide whether an unsaturated substance polymerises with or without a catalyst, because traces of impurities, *e.g.*, peroxides, can accelerate the polymerisation catalytically. It may be observed that ordinary vinyl acetate, when heated to 100-120°, polymerises within a few days. When air is carefully eliminated a sample can be heated for several months without polymerisation taking place.<sup>73</sup> Therefore numerous investigations will be required in order to supplement the qualitative facts with quantitative data. Certainly the work at present being carried out by Rudeal and his collaborators, by Mark and others, will contribute much to increase our knowledge in this direction, which is also of great importance to industrial chemistry.

An explosion-like course of the polymerisation was repeatedly observed in the cases of the polymerisation of monomeric formaldehyde, of acrylic esters and ethylene oxides. The reason for this is that these polymerisations are strongly exothermic reactions. On account of this large development of heat the more volatile compounds evaporate to a large extent, giving rise to very high vapour pressures.<sup>74</sup>

In my paper I mentioned that very high molecular weight products can arise only by the peculiar chain polymerisation process, but not by polycondensation reactions. As Mr. Houwink correctly remarks, this statement holds only for linear macromolecules but not for three-dimensional macromolecules. In the phenol formaldehyde polycondensation reaction

<sup>72</sup> This vol., p. 296.

<sup>73</sup> H. Staudinger and A. Schwalbach, *Lieb. Ann.*, 1931, **488**, 32.

<sup>74</sup> Compare H. Staudinger and O. Schweitzer, *Ber.*, 1929, **62**, 2307.

very large three-dimensional macromolecules can be formed. On the other hand, it is very unlikely that linear high molecular weight products of eucolloidal character can be built up by polycondensation processes, because in this case the number of reactive parts of the molecules is comparatively small, as H. Mark has also pointed out.

In regard to the question of Professor Waterman as to the transformation of caoutchouc into hydrocaoutchouc I have to remark that the catalytic hydrogenation is carried out with very dilute solutions, a condition under which cyclisation cannot occur. In addition a series of polymeric homologous caoutchoucs of different average molecular weights was transformed into the polymeric analogous hydrocaoutchoucs, which thus is a proof of the macromolecular structure of caoutchouc.<sup>75</sup>

In regard to the remarks of Dr. de Boer, it would, of course, be very interesting if one and the same macromolecule could exist in one case as a linear colloid, and in another as a sphero-colloid. In homopolar solvents polystyrene molecules are linear colloids. It is possible to imagine in a heteropolar solvent that a thread molecule could roll up, thus assuming a sphere-like form, since in this case only weak van der Waals' forces exist between the solvent and the dissolved substance. However, experiments in this direction have not yet proved successful. In the polystyrene latex the colloid particles are not single molecules of polystyrene rolled up in the form of spheres, but a single latex drop has approximately spherical shape and is estimated to contain  $10^4$ - $10^5$  single molecules forming one micelle.

I regret that Professor Kurt Meyer<sup>76</sup> once more brings forward a question which I consider to have been completely answered long ago by the discussions of recent years. K. H. Meyer is of the opinion that the macromolecular nature of high molecular weight compounds is not definitely proved by their transformation into polymeric analogous products, and he quotes, e.g., that in the transformation of a soap micelle into fatty acid esters and also in the transition of a fatty acid into its derivatives a change of the particles occurs. To this I can only point out that the proof of the macromolecular structure of synthetic as well as natural high molecular weight compounds, such as rubber and cellulose, depends not upon a single but upon numerous reactions giving results that agree well with each other.<sup>77</sup>

Numerous series of polymeric homologous products have been prepared, and the change of physical properties with molecular weight has been carefully investigated. Since these changes take place in a strictly regular manner, one is entitled to draw the conclusion that high molecular and low molecular weight compounds possess a similar structure. According to this, the end members of a polymeric homologous series (e.g., of rubber and cellulose) have the same molecular structure as the members at the beginning of the series. Their structure is a macromolecular one and not a micellar one. Hence, in addition, the transformation of various members

<sup>75</sup> Compare H. Staudinger and E. O. Leopold, *Ber.*, 1934, **67**, 304.

<sup>76</sup> In footnote <sup>70a</sup> K. H. Meyer quotes from *Annalen* 1929, but he does not add that in this very publication, on pp. 259-271, detailed reasons were put forward to show that, based on experiments with the polyoxymethylenes, a macromolecular structure must also be assumed in the case of cellulose. This assumption was often made in times gone by, but in the past 10 years it has frequently been rejected, especially by X-ray workers. The macromolecular structure of cellulose was finally proved by the preparation of polymeric homologous series and their transformation into polymeric analogous products\* and moreover, the molecular weight of the cellulose molecule was determined by viscosity measurements. The earlier hypotheses of K. H. Meyer as to the size of the cellulose molecule, which he quotes, have never been put on a sufficiently sound experimental basis.

\* Compare H. Staudinger, *Naturwissenschaften*, 1934, **22**, 797 and *Trans. Faraday Soc.*, 1933, **29**, 18.

<sup>77</sup> Compare H. Staudinger, *Die hochmolekularen organischen Verbindungen, Kautschuk und Cellulose*, Springer, 1932.

of one polymeric homologous series into the corresponding polymeric analogous products shows that in the case of the high molecular weight products analogous chemical transformations can be carried out, as can be done with compounds of low molecular weight.

Furthermore, K. H. Meyer points out that the opinion set forth in my publications is not in contradiction to his, since solid crystalline cellulose is built up of micelles which, also, in his opinion, are split into single molecules when brought into solution. I must remind Professor Meyer of his earlier publications of 1928,<sup>78</sup> in which the hypothesis was set forth that, in analogy with the ideas of R. O. Herzog,<sup>79</sup> the micelles in a solution and in the solid state were said to have a similar size. Such a micelle was supposed to be built up of 40-60 primary valency chains, each chain containing 30-50 glucose residues.<sup>80</sup> This conception was generalised and such a micellar structure was put forward as applicable to all high molecular weight compounds. The colloidal properties of their solutions were thought to be dependent on the micellar structure of the colloid particles. In contradiction to this, I have furnished proof that the colloidal particles of a dilute solution of cellulose and its derivatives just as in the case of the solutions of synthetic high polymers are identical with the macromolecules themselves, and that the colloidal properties of these solutions, especially their high viscosity, do not depend on the micellar structure of the particles, but upon the fact that they are built up of long thread molecules. To give a parallel, the difference between the two conceptions may be presented as follows: a micelle, according to K. H. Meyer, is represented by a series of short rods collected into a bundle similar to matches in a box. A macromolecule, on the other hand, is to be compared with a very long thin rod, 500 to 1000 times longer than it is thick.

In this connection, I should like to discuss the remark of Professor Pringsheim with regard to the constitution of inulin. Although unable to answer his question, since investigations on inulin have not yet been carried out in the Freiburg laboratories, I want to point out that the evidence obtained for the macromolecular structure of cellulose cannot be directly applied to prove a macromolecular structure of inulin. Moreover, it will be necessary to elucidate also in this case the structure and size of the molecules according to the methods of organic chemistry before relationships between the physical properties and the constitution of the molecules can be obtained; only when this has been established can Dr. Pringsheim's question be answered.

I would like to emphasise the fact that in the field of the high molecular weight compounds the same outlook should be adopted as for the low molecular weight compounds: therefore, it must be clearly realised *that the physical and chemical properties of high molecular weight substances depend upon the structure and the size of their macromolecules, and not upon a type of micellar structure*, as has been previously suggested by K. H. Meyer and many colloid chemists.

In conclusion, I may draw attention to the following interesting remarks of K. H. Meyer<sup>81</sup> which characterise clearly his earlier point of view on the colloid particles of solutions of high polymers: "It is unsuitable to designate as molecules the units which we designate as main valency chains and which possess different chain lengths; for their average size cannot be determined by the osmotic methods of molecular weight determinations, moreover these furnish the weight of a micelle composed of many main valency chains."

into the strength of the internal bonds of a material, a problem of great importance for high polymers.

Taking into account the attractive and repulsive forces  $F$  between two atoms 1 and 2 of a material, the interatomic distance  $a$  will be as shown in Fig. 1.

In order to remove atom 2 from the sphere of attraction of atom 1, an attractive force must be overcome. When the distance has been increased by an amount  $a' - a$ , the attractive force reaches a maximum  $F_m$  after which the force decreases again. One may therefore say that  $a' - a$  corresponds to the elongation  $\epsilon$  when the yield value is reached.  $F_m$  represents the rupture strength per pair of atoms.

As follows from an article by de Boer,<sup>2</sup> the modulus of elasticity of the bond between atoms 1 and 2 is represented by the distance  $E$ , when no account is given to Poisson's Ratio.

The rupture energy  $e_r$  for this pair of atoms can now be calculated as

$$e_r = - \int_a^{\infty} F dx \quad . \quad . \quad . \quad (2)$$

and is represented by the cross-hatched area in Fig. 1.

For the aliphatic C—C bond, which is of special interest in our problems,  $e_r = 6.95$  electron volts (160 kg. cal. per gram equivalent), cf. de Boer.<sup>2</sup>

## § 2. Theories about the Internal Structure of Asphalts, Resins and Glass.

The amorphous materials may be divided into two groups, namely, one in which the structural units (or groups of these units) cohere by means of primary bonds, and one in which the coherence is effected by means of secondary bonds (by van der Waals' forces, for example). There is a great difference in energy content between these two kinds of bonds (cf. the paper presented to the present discussion by J. H. de Boer<sup>2</sup>, and it is one of our purposes to deal with the elastic properties of the amorphous materials on the basis of that energy difference. For this reason it is necessary to point out briefly the part played by the different bonds in the formation of the substances under discussion.

<sup>2</sup> J. H. de Boer, *Trans. Faraday Soc.*, this volume. Dr. de Boer remarked in a discussion that one cannot assume merely from Fig. 1 that a large energy content will always result in a large modulus  $E$ . To understand this relation one has to consider that a large energy content will result in a small interatomic distance  $a$  and, as a consequence of this, the tangent in 2 will be steeper.

FIG. 1.—Diagrammatic representation of the Forces between two atoms 1 and 2.

(1) In the case of *asphalts*, asphaltenes are assumed to be present, in which the coherence is probably effected by primary bonds,<sup>3</sup> together with petrolenes,<sup>4</sup> which consist of asphaltic resins and oily constituents bound to each other and to the asphaltenes by means of secondary bonds. The so-called steam refined asphalts contain roughly 20 per cent. of asphaltenes, and this content may be increased by means of oxidation (combined with a destructive distillation) to about 30 per cent. such as is encountered in many of the so-called blown asphalts.

(2) The case with *resins* (only the three-dimensionally polymerising resins are considered here) is much more complicated. The author<sup>5</sup> has already described in full how one may assume non-crystalline micelles to be present in a non-hardening resin and in the fusible (and soluble) *A* stage of a hardening resin as well. These micelles are assumed to cohere by means of secondary bonds. These bonds may be compared with those in asphalts. The case of the hardening resins is different from that of the non-hardening resins in so far as in the hardening resins reactive spots are supposed to be present on the surface of the micelles which enable the micelles to react with each other. As a consequence of the resulting growth of the micelles the resin passes from its (assumed) isogel state through the *B* stage (somewhat fusible and only partly soluble, still an isogel) into the infusible *C* stage. Since this resinification will be dealt with in detail later, a scheme which probably represents the chief reaction<sup>6</sup> is reproduced in Fig. 2.

According to this scheme only primary bonds would be present in the macromolecule formed. We shall see in how far the data concerning mechanical properties support this conception. In the following discussion the resins in the *A*, *B* and *C* states will often be denoted as *A*, *B* and *C* resins respectively.

(3) The most detailed description of *glass* has been given by Tammann.<sup>7</sup> According to this author, during the cooling of a liquid glass, when a certain temperature  $T_f$  is reached, the freely rotating molecules begin to cohere to form larger units (gel or isogel state; compare note 5). At a second (lower) temperature  $T_g$  this coherence should be complete so that below  $T_g$  no freely rotating molecules should be present. The region between  $T_f$  and  $T_g$  is usually called the *transformation interval* and corresponds to a viscosity of about  $10^{13}$  poises. Tammann obviously assumes primary bonds to be present in the molecules. In the temperature interval from  $T_f$  to  $T_g$  the formation of secondary bonds between the molecules is accepted by some authors.<sup>8</sup> Another opinion, somewhat contradictory to the above, is that of Zachariasen,<sup>9</sup> who assumes for certain kinds of glass a coherence of ions (called atoms by him, as is often

<sup>3</sup> F. J. Nellensteyn, footnote 1.

<sup>4</sup> C. Mack, *Proc. of techn. Session Assoc. of Asphalt Techn.*, Dec., 1933, 11. Mack, *J. Phys. Chem.*, 1932, **36**, 2901.

<sup>5</sup> R. Houwink, *Physikalische Eigenschaften und Feinbau von Natur- und Kunstharzen*, Leipzig, 1934.

<sup>6</sup> There are other opinions about the reaction scheme. In so far, however, as they also assume a molecular growth by means of primary bonds, our general considerations to be developed in this paper, *mutatis mutandis*, will remain the same. In addition, secondary reactions will of course also take place.

<sup>7</sup> G. Tammann, *Der Glaszustand*, Leipzig, 1933.

<sup>8</sup> See for a survey of the problem, E. Berger, *Z. techn. Physik*, 1934, **15**, 443. In this survey Berger assumes both "chemical" bonds and "physical" bonds to play a rôle.

<sup>9</sup> W. H. Zachariasen, *J. Amer. Chem. Soc.*, 1932, **54**, 3841; *J. Chem. Physics*, 1935, **3**, 162.

done in crystallography) which is of course effected by primary bonds. A more general theory of glass-formation was given by Hägg<sup>10</sup> who in some cases introduces two kinds of primary bonds, homopolar and heteropolar. Without deciding between these two last-mentioned theories, we may, however, fully accept the assumption made by both in regard to the rôle of primary bonds in glass formation. The high softening temperature is the best proof of the great energy content of these bonds.

FIG. 2.—Condensation of phenol formaldehyde resin.

This representation is very diagrammatic. The benzene nuclei must be imagined to be linked in three dimensions, but not in a regular manner, so that there is no question of a crystalline pattern. This has been proved by means of X-ray measurements by W. G. Burgers and R. Houwink.<sup>6</sup>

From this point of view a great similarity must be expected between the mechanical properties of a C resin and those of glass. In order to make the comparison the following energy contents may be mentioned. For a C phenol-formaldehyde resin the C—C bonds may be assumed to have an energy content of about 160 kg. cal. per gram equivalent (see above). For glass one may assume an order of magnitude of about 200 kg. cal. for the alkali ions in an alkali glass. This value increases with decreasing alkali content. On this basis very high values for Young's modulus and tensile strength may be expected in both cases; these quantities will be of a different order of magnitude from those for asphalts and non-hardening resins, where secondary bonds predominate.

### § 3. Observations on the Modulus of Elasticity and Strength of Asphalts, Resins and Glass.

In Table I. some figures (taken partly from the literature) have been tabulated for the modulus of elasticity and the tensile strength of the materials under discussion as well as of some other materials for comparison. In some cases values at the temperature of liquid air ( $-195^{\circ}\text{C}.$ )

<sup>10</sup> G. Hägg, *J. Chem. Physics*, 1935, 3, 42.

have been added, since at this temperature plastic deformations are practically excluded, a fact which is uncertain at room temperature. More-

<sup>15</sup> J. Karger and E. Schmidt, *Z. tech. Physik*, 1923, 6, 124. These values were calculated from observations at room temperature after an ingenious correction for the plastic part of the deformation had been made. E. Valko, *Melland Textilber.*, 1932, 13, 461.

<sup>16</sup> S. Timoschenko and I. M. Lossels, *Festigkeitslehre*, 1928.

over, at this low temperature one may be sure that, in resins for example, there will be no longer any freely rotating particles, so that a comparison with glass at room temperature seems more reasonable.

In the first place, the low values of  $E$  and  $F$  for asphalts, and the non-hardening resin (colophony) demonstrate the weakness of the secondary bonds in these materials. In the second place, the values for hardening resins at room temperature are interesting. In the case of the phenol-formaldehyde resin, for example, the increase of  $E$  by polymerisation from 290 to 595 and of  $F$  from  $10^{-2}$  to  $6.7 \text{ kg. mm.}^{-2}$  corresponds to the replacement of secondary bonds by primary bonds as was assumed in § 2. The fact that after a heating process lasting 60 min. at  $150^\circ \text{C.}$  no further increase in  $E$  takes place, leads to the conclusion that the process of polymerisation has come to an end within that time.

Cooling in liquid air causes  $E$ , in the case of the phenol-formaldehyde resin, to increase to  $1050 \text{ kg. mm.}^{-2}$  and  $F$  to  $7.8 \text{ kg. mm.}^{-2}$ . This may perhaps be explained by assuming that at room temperature the deformation was still somewhat plastic, although, on the other hand, Hooke's law was found to be applicable up to rupture. We are therefore inclined to consider the deformation of such resins in the  $C$  stage as *truly elastic*. Some (calculated) stress-strain curves have been reproduced in Fig. 3. The elongation at the proportional limit (here elongation at rupture) is for all  $C$  resins at liquid air temperature 0.5 to 0.7 per cent., i.e., of the same magnitude as for the best spring steel.

FIG. 3.—Stress-strain curves for hardening Resins in the  $C$  stage (in comparison with other materials). The curves for resins have been constructed by starting from the observed deflection figures; compare footnote 11.

#### § 4. Explanation of the Low Tensile Properties for Hardening Resins on the Basis of a "Lockerstellentheorie".

Table II. gives a comparison of the tensile strengths of certain materials, as they are observed experimentally, with the tensile strengths which have been calculated on a basis of theoretical considerations. For the resins, the values at liquid air temperature have been tabulated in order to avoid the possibility of plastic deformations.

Many theories<sup>18</sup> have been proposed to explain the discrepancies between observed and calculated values in the case of *crystalline* substances. We shall not discuss all these at length, but mention only the *Lockerstellen* theory of Smekal which seems to be of especial interest in

<sup>18</sup> See next page.

connection with our subject. In this theory structural defects (*Lockerstellen*) are assumed to be present in a crystal. In the neighbourhood of these defects a concentration of stresses is assumed to occur, leading to the observed low "technical strength."

TABLE II.—COMPARISON OF EXPERIMENTAL AND THEORETICAL VALUES OF TENSILE STRENGTH  $F$ .

	$F$ (observed).	$F$ (calculated).
Phenol-formaldehyde resin (C stage) at — 195° C.	7.8 kg. mm. <sup>-2</sup>	4,300 kg. mm. <sup>-2</sup>
Cresol formaldehyde resin (C stage) at — 195° C.	3.8 ..	3800 ..
Glass normally .. .. .	3'5-8'5 ..	} 1100 <sup>17</sup> ..
Glass <sup>17</sup> under special conditions ..	350-630 ..	
NaCl crystal <sup>18, 2</sup> normally .. ..	0.6 ..	} 200-400 ..
NaCl crystal under special conditions ..	up to 100 ..	

An explanation of the similar discrepancy between the observed and calculated strength of glass (*cf.* Table II.) may be sought in the theory of Griffith.<sup>17</sup> According to this conception, the discrepancy is partly due to the fact that rupture does not take place simultaneously over the whole cross-section of an amorphous body, but that it starts from accidental cracks (flaws) at which a concentration of stresses is again assumed to occur. Some authors draw special attention to cracks on the surface, while others (*cf.* Joffé, *loc. cit.*<sup>18</sup>, page 78) assume the faults to be distributed throughout the bulk of the glass, and to become especially liable to cause rupture when they reach the surface. In our opinion there are several reasons for accepting a similar picture in the case of C resins. The flaws in this latter case will not, however, be accidental and due to some exterior influence (as is assumed by some authors), but will be structural features of statistical nature. They may, therefore, be compared with the *Lockerstellen* of Smekal and we shall consider them as such.

One of the reasons for the existence of these flaws may lie in the fact that not all the CH<sub>2</sub> bridges which are possible on the basis of Fig. 2 will be formed. This becomes comprehensible if we consider Fig. 4 and remember that the benzene nuclei are irregularly arranged and do not lie all in one plane (as should be evident from the figure). At the spot designated by *L* one might assume for instance that the benzene nuclei 5 and 6 are in such relative positions that a chemical reaction between the CH<sub>2</sub>OH and the H groups is impossible. This might be due to the fact that the CH<sub>2</sub>OH group lies above the plane of the drawing and the H group below it. Further, the presence of occluded reaction products (H<sub>2</sub>O) in such a resin might give rise to "holes" in the macro-molecule.

<sup>17</sup> A. A. Griffith, *Phil. Trans.*, 1921, 221A, 163; *Proc. Int. Congress Appl. Mech. Delft*, 1924, p. 55.

<sup>18</sup> Compare A. Joffé, E. Orowan and A. Smekal in: *Proc. Internat. Conference on Physics*, Part II., London, 1934; A. Smekal in: *Handb. der Physik*, 24<sup>II</sup>, Berlin, 1933. A recent summary by W. G. Burgers and J. M. Burgers is found in the First Report on Viscosity and Plasticity, Roy. Academy of Sciences, Amsterdam, 1935.

<sup>19</sup> This value was extrapolated from experimental figures. Calculations, based on atomic considerations, would lead to much higher values.

Another, more important, reason for the occurrence of *Lockerstellen* may be the following. As long as a resin molecule of a certain size is growing by the continual addition of small molecules (for example:

in Fig. 2) which possess but one benzene nucleus, the chance that a single molecule will be added at each active spot of such a growing mole-

FIG. 4.—A resin macromolecule in which a defect ("Lockerstelle") is assumed.

cule will be the greatest possible. This chance becomes smaller according as the molecule to be added begins itself to increase in size. This may easily be seen by considering models of atoms. It may, however, also be illustrated by Fig. 5a. If one assumes that at a given moment the large molecules *A* and *B* (whose chemically active points are marked with  $\times$ ) are grown together at points 1, 2 and 3, one may then assume that no further attachment of *A* to *B* is possible since the freedom of movement necessary for such a development is lacking. The steric conditions make the chance of the addition of new single molecules at points 4, 5, 6 and 7 extremely small, and one may even imagine that this probability becomes equal to zero. From

FIG. 5a.

FIG. 5b.

FIG. 5a.—Further formation of "Lockerstellen" in a hardening resin.  $\times$  represents chemically active spots; 1, 2 and 3 points of juncture; 4, 5, 6 and 7 spots where further growth is extremely improbable.

FIG. 5b.—A macromolecule with "Lockerstellen."

this picture it follows that weak spots (*Lockerstellen*) may be expected to be formed in a resin molecule, especially at the moment at which the nets are growing together (cf. the following paper).

If we consider the values calculated by de Boer<sup>2</sup> for the tensile strength on the assumption that only van der Waals' forces between "blocks" of the macromolecule are active, we find a theoretical tensile strength for the phenol-formaldehyde resin of  $> 30 \text{ kg. mm.}^{-2}$ , and

for the cresol-formaldehyde resin of  $> 20$  kg. mm.<sup>-2</sup> Even these values are greater than those found experimentally. In order to explain this we should be inclined to assume that a similar consideration is valid for the van der Waals force as that which is given for the primary bonds with reference to Fig. 5. We should thus be inclined to assume also that *as a consequence of the presence of Lockerstellen the maximum combining energy which might be obtained by means of van der Waals' bonds is not reached.*

It is evident that a concentration of stresses at the faults is assumed during deformation in a similar way as is postulated in the theories of Griffith and Smekal and other theories about the subject. The fact that the *Lockerstellen* in the amorphous materials described are less regularly arranged (see Fig. 5b) than is often assumed to be the case in crystals may perhaps be partly responsible for the observation that resin macromolecules (and glass) are brittle and show no glide planes such as are observed with some metals.

Attention must be drawn to the fact that  $\frac{F \text{ observed}}{F \text{ calculated}}$  for glass is  $> 200$ , for a resin macro-molecule it is 550 to 1000, and for a sodium chloride crystal 500.

Certain calculated and observed values of Young's modulus may be compared at this point. The following values for the phenol-formaldehyde resin are taken from the paper of de Boer :

$E$  calculated for primary bonds 11,000 kg. mm.<sup>-2</sup>

$E$  calculated for van der Waals' forces  $> 45$  kg. mm.<sup>-2</sup>.

The experimental value of about 500 kg. mm.<sup>-2</sup> (in liquid air 1050 kg. mm.<sup>-2</sup>) may point to the fact that the coherence in a resin molecule is effected for a part by van der Waals' forces. The discrepancy between the observed and calculated values of tensile strength is much greater, and it may be ascribed to the fact that the strength is practically determined only by the concentration of stresses at the most "dangerous" *Lockerstellen*, whereas the modulus of elasticity is given through the co-operation of the moduli of several bonds in the molecule.

The explanation of the nature of the above-discussed faults in glass, may be in part similar to that in the case of C resins. It may take into account the formation of net fragments at  $T_g$  which are assumed to grow into each other gradually during cooling. In this connection, attention may be drawn to a paper by Lillie<sup>20</sup> who (after making many reservations) calculates an increase in aggregate weight from 15,000 to 112,000 when the temperature of glass falls from 1100° C. to 500° C. Such a process of growing into each other of colloidal net fragments would offer an explanation of the fact that (because of unfavourable steric conditions) neither all the ionic bonds nor all the van der Waals' bonds can reach their maximum binding energy. It would go beyond the scope of this paper to attempt to explain all the experimental results of investigations, such as those of Griffith and Joffé, connected with this subject. We hope to have an opportunity to try this at another time.

<sup>20</sup> H. R. Lillie, *J. Amer. Cer. Soc.*, 1933, 16, 619. A growing together of large particles has also been observed in the formation of crystals from certain materials, cf. W. von Behren and J. Traube, *Z. physik. Chem.*, 1930, 176A, 1. The attention of the author was drawn to these observations by Prof. Traube during the meeting.

### Summary.

1. A general description is given of tensile properties and modulus of elasticity on a basis of cohesive forces of matter.

2. The most prominent theories as to the internal structure of asphalts, resins and glass are discussed briefly.

3. The elastic properties in question have been studied for hardening resins in particular. The modulus of elasticity and the tensile strength of a phenol-formaldehyde resin, for example, are found to be 1050 kg. mm.<sup>-2</sup> and 7.8 kg. mm.<sup>-2</sup>, respectively, at a temperature of  $-195^{\circ}$  C. The results have been compared with similar observations for the other materials to be found in the literature.

4. A *Lockerstellen* theory is introduced in the case of resin macromolecules in order to explain the fact that the tensile strength of a phenol-formaldehyde resin, for example, is about  $\frac{1}{10}$  of its theoretical value (calculated for the primary bonds). Structural causes for the presence of such *Lockerstellen* are indicated and discussed.

5. The fact that for Young's modulus  $\frac{1}{10}$  of its theoretical value is found, may be considered as an indication that, in addition to primary bonds, secondary bonds also play a rôle in resin macromolecules.

Our sincere thanks are due to Dr. J. H. de Boer of the Philips' Laboratories, for his critical assistance, and to Mrs. H. E. Teves-Acly for the translation of the manuscript.

## HIGH ELASTICITY OF THREE-DimensionALLY POLYMERISED AMORPHOUS MATERIALS IN RELATION TO THEIR INTERNAL STRUCTURE.

By R. HOUWINK.

[Communicated by the Philips Works (Moulding Dept.) of the N. V. Philips' Gloeilampenfabrieken Eindhoven, Holland.]

Received 10th July, 1935

### Introduction.

In this paper the high elasticity of *asphalts, resins and glass* will be dealt with. An attempt will be made to explain the phenomena observed on a basis of the theories about the internal structure of these materials, as these were dealt with in the foregoing paper.

### § 1. High Elasticity of Matter ; Relaxation.

In addition to the true elasticity of rigid bodies attention must be drawn to the *high elasticity* (*ausgiebige Elasticität*) of certain soft materials. It is difficult to give a precise definition of high elasticity since no logical point of departure has yet been discovered. We shall therefore confine ourselves to the following practical description:

An elastic deformation will be called highly elastic when it exceeds a value of about 1 per cent. This limit is chosen in order to exclude crystalline materials (metals) which are considered not to be highly

elastic and for which no higher values than 1 per cent. are usually observed<sup>1</sup> (*cf.* Table I. of the foregoing paper.).

Highly elastic deformations are often, as can be observed with raw rubber, far from truly elastic.

The well-known fact that the elastic after-effect can often be observed practically, only after a rise in temperature, will be accounted for by the introduction of the term *thermo-recovery*.

The credit falls to Whitby<sup>2</sup> for having pointed out the fact that many materials, which are hard solids at room temperature, have a so-called "elasticity temperature" at which they become rubbery elastic. In connection with the above definitions this temperature will be denoted in the future as the *high elasticity temperature*.

The treatment of all (partly amorphous) materials which show high elasticity would go beyond the scope of this paper. For materials such as wool,<sup>3</sup> rubber and muscles,<sup>4</sup> where the high elasticity seems to be a property of the polymerised chain molecules themselves, reference is made to other sources. The same holds for materials in which the molecules are long in shape and perhaps rigid.<sup>2, 5</sup> Since it is frequently thought that high elasticity is only encountered in materials having long molecules or micelles<sup>6</sup>—there are even theories which seek to explain high elasticity itself upon this principle<sup>7</sup>—it seems extremely important to show that high elasticity may also be observed to a considerable extent in the case of materials which are polymerised in three dimensions and which therefore probably have globular micelles. It is the purpose of this paper to deal especially with this group of amorphous materials. It will appear that high elasticity and also thermo-recovery are much more frequent properties of matter than is usually assumed in the literature.

In the case of asphalts there are no reasons to deny the presence of globular micelles. Among the resins, as was already mentioned, there are representatives (e.g., polystyrene, polyvinyl-acetate) for which the micelles are generally accepted to be long in shape on the basis of the work of Carothers<sup>8</sup> and Staudinger.<sup>9</sup> For other resins, however, such as the natural resins, phenol and cresol-formaldehyde resins and "glyptals," the globular micelle form seems very probable on the basis of investigations by the author.<sup>10</sup> The fact that Newtonian flow may be observed<sup>11</sup>

<sup>1</sup> From a theoretical point of view this definition is incorrect, for, as Zwicky (*Physik. Z.*, 1923, **24**, 131), showed, one can calculate for NaCl an elastic extensibility of 14 per cent. As such extensions are not actually observed however, our definition seems to be practical.

for certain kinds of glass in a molten condition is an indication that globular micelles are also present in that case. It must, however, be mentioned that some authors suggest the possibility of relatively short, linear molecules.<sup>12</sup>

From considerations as to the oscillations of the atoms one can derive the following relation<sup>13</sup> for monomeric substances:

$$e = 3KT \text{ per atom } (3KT = 5.96T \text{ cal. per gram atom}), \quad (1)$$

where  $e$  is the mean interatomic energy as a consequence of heat motion,  $K$  the Boltzmann constant, and  $T$  the absolute temperature. At the melting-point  $T_m$  of such a system, therefore,<sup>13a</sup>

$$e_m = 3KT_m.$$

As a first approximation one may say that at a given temperature  $T$ , lower than  $T_m$ , the energy content of the bond is equal to

$$e_s - e = 3K(T_m - T).$$

Since a rise in temperature causes an oscillation of the atom whose alternating impulses may exceed the mean value  $3KT$ , local migrations may already have taken place before  $T$  has reached the value of  $e_s/3K$ .

The following consequences of heat motion are important with regard to our present problems. If a body is stretched to a length  $l - dl$  the atoms undergo a certain mutual displacement which is connected with a potential (elastic) energy denoted by  $e_p$ . If the system is maintained at this elongation there are two possibilities:

(a) If there are atoms for which  $e_p$  is larger than  $e_s - 3KT$  these atoms can migrate and a partial plastic deformation on release of stress may then be observed. Energy is dissipated as heat.

(b) The atoms for which  $e_p$  is smaller than  $e_s - 3KT$  will absorb the energy  $e_p$  as elastic energy, and this will give rise to internal forces which balance the external ones.

As frequently, however, as an accidental extra impulse caused by heat motion is larger than  $e_s - 3KT - e_p$  the atom will migrate. The stored-up potential energy will then be partly transformed into heat. A continually decreasing tension will be necessary to keep the material in its deformed state. This phenomenon is known as *relaxation of stress*, and is expressed by the Maxwell formula

$$F = F_0 e^{-\frac{t}{\lambda}} \quad (3)$$

in which  $F$  is the internal tension at the moment  $t$ ,  $F_0$  is the original tension, and  $\lambda$  a constant, the relaxation time. The value of  $\lambda$  is connected with the energy content  $e_s - 3kT$  of the interatomic bonds. It follows from the above considerations that *the maximum amount of elastic energy  $e_p$  to be stored up in a body at a given temperature  $T$  may be assumed to be a function of the value of  $e_s - 3kT$* . This conclusion will be utilised later. The stored-up energy will, however, gradually be transformed into heat.

The fact that in amorphous bodies potential troughs of varying depths

<sup>12</sup> G. Hagg, *J. Chem. Physics*, 1935, 3, 42.

<sup>13</sup> A. Eucken, *Lehrbuch der Chem. Physik*, Leipzig, 1932, p. 137.

<sup>13a</sup> Strictly  $T_m$  indicates the temperature just below the melting-point, so that the heat of melting is left out of consideration.

$e_r$  may be assumed for various atoms<sup>14</sup> complicates this simple conception to a considerable degree.

## § 2. Observations on High Elasticity and Thermo-elasticity of Asphalts, Resins and Glass.

As has already been mentioned, some authors always connect the possibility of high elasticity phenomena with the presence of long chain molecules. It will now be shown that such phenomena can also be observed with materials for which in section 1 the probability of a globular micelle form has been discussed.

### (1) Asphalt.

Experiments by Saal<sup>15</sup> have shown that the high elasticity of asphalt is more pronounced the more the bitumen deviates from a Newtonian

FIG. 1—High elasticity of blown and of steam-refined asphalt (data of F. J. Nellensteyn)

liquid. The data reproduced in Fig. 1 for the high elasticity of certain kinds of bitumen were collected by Nellensteyn<sup>16</sup> by means of a Hoekstra balance plastometer<sup>17</sup>. In this instrument a specimen of the material is compressed for a given time. The compressive force is then released and the recovery can be accurately measured. Fig. 1 shows the curves obtained at 30° C. with a blown and with a steam refined asphalt respectively, particulars of which are tabulated in Table I.

Thus an elastic recovery of about 10 per cent. can be observed. It must be noted that this value was higher for the blown asphalt than for

the steam refined, *although the former was softer*. We shall return to this point in section 4. Another important point is that at 30° C. the viscosity  $\eta$  must be very high. From the well-known fact that at the

## (2) Resins.

It is a well-known fact that the heating (causing polymerisation) of resins of the phenol-formaldehyde type produces a highly elastic, "rubberlike" state, the so-called *B* state. This phenomenon was investigated by Houwink,<sup>10</sup> who was able to show that high elasticity is observed only when a sufficiently large proportion of large micelles may be assumed to be present. Elastic deformations of about 30 per cent. (calculated with respect to the original dimensions), which are to a large extent thermo-elastic phenomena, are described in the above-mentioned work. On further polymerisation, however, the deformability decreases again, and, as is shown in the foregoing paper, only a small true elasticity of the order of 1 per cent. can be observed in the *C* stage. By means of a more efficient technique it has been possible, however, to observe a much more important high elasticity with *B* resins as follows.

Since in the above-mentioned experiments by the author it was not certain that the most suitable high elasticity temperature had been reached, an attempt was made to carry out experiments at a much higher temperature. With the resins under consideration the reaction velocity increases rapidly with temperature, so that, on heating, the resin will quickly be completely transformed into the *C* stage. The observations must therefore be made very quickly. In order to bring the whole mass of the resin rapidly to the desired temperature, the heating was done by means of a pair of hot milling rolls (rubber mixer). When an *A* resin is thrown on the steam-heated rolls, it melts, and, as the polymerisation reaction progresses during milling the *B* stage and finally the *C* stage are reached. During this process samples were taken, of which one observer determined the elastic behaviour, and a second the temperature by means of wrapping the specimen around a thermometer. The temperature so measured is markedly higher than that of the rolls, because of the frictional heat and the heat of reaction developed in the material. The elastic behaviour was studied by marking off a length of 1 cm. on a specimen, stretching it quickly, and releasing it. The distance between the two marks is then measured after release. It must be noted that this technique is far from perfect,

<sup>10</sup> R. Houwink, *Physikalische Eigenschaften und Feinbau von Natur- und Kunstharzen*, Leipzig, 1934. See, for an abstract on thermo-recovery, R. Houwink, *British Plastics Yearbook*, 1935, p. 51.

since the deformation must be carried out very rapidly to exclude the effects of the cooling of the sample on the one hand, and of the progressing polymerisation on the other hand. The data obtained are therefore only approximate values. The alcoholic extract (cold extraction) of the specimens investigated in this way was determined in order to get some insight into the degree of polymerisation.

\* 1 poise = 1 dyne cm.<sup>-1</sup> sec.

The results of some experiments carried out on two cresol-formaldehyde resins (raw materials containing 40 to 45 per cent. meta-cresol and 58 to 60 per cent. meta-cresol, respectively), and on a phenol-formaldehyde resin (Resol type) have been summarised in Table II.

It is evident from these figures that a temperature of 100 to 125° C. is a suitable high elasticity temperature for these resins in the B stage. The highly elastic state could be maintained on the rolls during 8 minutes for the slower cresol resin I, but only during 2.3 minutes for the much quicker cresol resin II, and only during about half a minute for the extremely quick phenol resin. It is further evident that with the cresol resins I. and II. highly elastic deformations of about 200 and 240 per cent. respectively could be observed. The fact that these values were much higher than that for the phenol resin must be ascribed to the extremely quick reactivity of the latter, which makes the taking of samples at the right moment very difficult.

In Fig. 2 some observed data for the elastic recovery are represented, together with data for the change in the alcoholic extract during the steadily increasing polymerisation. It may be taken from Fig. 2 that high elasticity occurs only when a still quite considerable proportion of the resin is soluble. Roughly, a solubility of between 25 and 65 per cent. seems to be necessary for high elasticity of over 100 per cent.

Attention must be drawn to the decrease in the alcoholic extract during the process of polymerisation. This decrease is relatively small compared with the enormous changes in the elastic behaviour. At the utmost (cresol resin II.) a change of 40 per cent. in the alcoholic extract may be taken to correspond to a cycle of increasing high elasticity from zero to 240 per cent. and decreasing it from that value to zero again. This may perhaps be an indication that a very important change in internal structure during this stage of the condensation process is the growing into each other of the net elements. This supposition is supported by observations of the changes in viscosity of the resins. The viscosity  $\eta$  was measured at 60° C. by means of a plastometer and was found to be about  $10^6$  poises when the first signs of high elasticity could be observed. On further polymerisation only quasi-flow (non-Newtonian flow) was observed, which means that  $\eta$  becomes dependent upon the magnitude of the applied shearing stress. This fact has already been connected with the formation of continuous networks in a resin.<sup>19</sup>

### (3) Glass.

Trouton and Andrews<sup>18</sup> showed that high elasticity phenomena can also be observed in the case of glass. They could study the viscosity of glass

by applying a constant torque to a cylinder of soda glass, and observing the relative motion of the ends. After release of the torque they could

<sup>18</sup> R. Houwink, (*loc. cit.* 18), p. 138.

<sup>20</sup> In a previous study by the author (Houwink,<sup>18</sup> p. 134) the work of M. So was cited erroneously in this connection. The recovery data observed by So are too small to justify the term high elasticity. They lie between 0.06 and 0.22 per cent. instead of being 1 per cent. as was calculated by the author. In So's experiments the temperature was too high to obtain a significant high elasticity.

study the recovery. From these experiments the data in Table III. are given.

It must be noted that the two experiments were not carried out under exactly the same conditions. The torque in the first case was 10/6 times that in the second case. No direct comparison can therefore be made. It is important to note, however, that, just as with asphalt, the high elasticity is observed in a viscosity range of  $10^{11}$  to  $10^{12}$  poises, which is in the neighbourhood of the transformation interval, that is to say when the material is in the (assumed) gel state, where freely rotating structural units are assumed to co-exist along with "solid" units.

### § 3. Explanation of High Elasticity.

In order to explain the high elasticity observed in materials with globular micelles an example of deformation worked out mathematically by van Dongen<sup>21</sup> will be dealt with.

In Fig. 3 the deformation of a compact body  $P$  is compared with that of an "open" body  $Q$ . The end planes of  $Q$  are assumed to be open so

Fig. 3 - Elastic deformation of a compact body  $P$  and of an "open" body  $Q$ .

that it forms a sort of rectangular "tube". The substance of which the bodies  $P$  and  $Q$  are constituted is assumed to be incompressible and to possess a modulus of elasticity  $E$  and a yield value  $f$ . It is further assumed that the contraction ratio  $m$  of the material is 4 and that the space inside  $Q$  is filled with an incompressible fluid. Under the application of a certain shearing stress  $\tau$  the body  $Q$  will be deformed in quite a different way from  $P$ , and if one assumes that

the experimenter does not know that  $Q$  is hollow, he will, for example, follow the displacement of point  $A$  in his measurements, and draw conclusions from the measured deformation  $X$  under the influence of a given  $\tau$ . In such a case he will then find for  $Q$  a quite different modulus of elasticity and a quite different elastic deformation on the attainment of the yield value from that for  $P$ . If this "apparent modulus of elasticity" is called  $E'$  van Dongen has derived the following relation:

$$\frac{E}{E'} = \left( \frac{l}{a} - 1 \right) \left( \frac{1}{3} \left( \frac{l}{a} - 1 \right)^2 + 1 \right). \quad (4)$$

From this it follows that the apparent modulus of elasticity is, in the first approximation, proportional to  $a^3$ , i.e., to the third power of the thickness of the wall. The following expression may be derived for the "apparent" specific elongation upon attainment of the yield value:

$$\frac{\epsilon'}{\epsilon} = \frac{a}{l} \left( \frac{1}{3} \left( \frac{l}{a} - 1 \right)^2 + 1 \right). \quad (5)$$

<sup>21</sup> Our sincere thanks are due to Ir. J. R. J. van Dongen of Eindhoven, for his kindness in working out this example on a basis of theoretical mechanics.

in which  $\epsilon$  is the specific elongation of the material itself and  $\epsilon'$  is the apparent specific elongation. As a first approximation one may thus say that the apparent specific elongation at the limit of flow is inversely proportional to the thickness  $a$  of the wall.

On the basis of Hooke's law it follows that the "apparent yield value is proportional to  $a^2$ .

The equations given above are only approximately valid when the deformations are small with respect to the dimensions and when the thickness of the wall  $a$  is small with respect to  $l$ . They are still sufficiently accurate when  $\frac{a}{l} \leq 0.3$ .

From this point of view it becomes understandable that a much lower modulus of elasticity, a higher elastic elongation and a lower yield value are observed for a gel consisting of cells of a solid substance filled with a fluid, than for a material which consists entirely of solid matter. Expressing this in terms of energy one may say that in the case of the body  $Q$  a much larger deformation  $X$  is possible before a bond between the structural elements will have absorbed an amount of energy equal to  $\epsilon_s = 3KT$ , the amount necessary for its distortion, than in the case of the body  $P$ . The causes of the high elasticity of three-dimensionally polymerised materials may be more easily understood by analogy with such a model. We shall use this concept in our own treatment of the hardening resins, and then apply the knowledge gained thereby in the cases of asphalts and glass.

#### ( $\alpha$ ) A Resin in the A Stage.

Fig. 4a represents a liquid resin in which chiefly freely rotating molecules denoted as  $\alpha$  units are assumed to be present. In such a liquid resin there may be an equilibrium between the number of  $\alpha$  units present and the number of so-called  $\beta$  molecules, which are molecules attached either to each other or to  $\gamma$  units (see below) by means of secondary bonds. As long as the equilibrium

is definitely in favour of the  $\alpha$  units, so that no yield value can be measured, the resin may be called a liquid. It is supposed, that even in such a liquid resin some molecules may be linked to one another by primary forces. Such a combination forms a  $\gamma$  unit.

When a shearing couple  $\tau \leftrightarrow \tau'$  acts on the liquid A resin it is obvious that it will cause the units to flow, and on release of the stress no elastic phenomena are to be expected.

Upon cooling the liquid resin the situation represented in Fig. 4b will gradually be reached where the number of  $\beta$  units has increased to such a degree that they begin to act as bridges between the  $\gamma$  groups. In this way a kind of network may be formed in which the structural elements cohere for a great part by means of secondary forces. Those parts of the structure where "holes" are present (filled with  $\alpha$  units) are comparable with the open structure of  $Q$  in Fig. 3. One might therefore expect to observe the phenomenon of high elasticity. The fact that this is not the case to a very considerable extent must in our opinion be ascribed to the following. In the temperature range in which  $\alpha$  and  $\beta$  units co-exist, the energy  $\epsilon_s$  of the bonds between the  $\beta$  units (about 1 kg. cal.

per gram equivalent  $\approx$  heat of fusion of phenol) is only slightly higher than the kinetic energy  $3KT$  of the heat motion of these units. Therefore the network cannot store up energy of elastic deformation  $e_e$  to a considerable extent within this range. If a quantity of energy  $e_e$  is stored up, it will very easily be dissipated by relaxation. Most of the energy added to the system as a whole will be expended in the form of a plastic deformation of the body.

Further cooling of the system will lower the value of  $3KT$ , and therefore increase the energy difference  $e_e - 3KT$ , thereby favouring the possibility of the storing up of energy and the consequent high elasticity. At

FIG. 4.—Scheme for the explanation of the elasticity phenomena of a three-dimensionally polymerising resin.

$\tau \sim \tau'$ . Shearing couple

$\alpha$  units, freely rotating molecules (soluble)

$\beta$  units, fixed by means of secondary bonds (soluble)

$\gamma$  units, fixed by means of primary bonds (insoluble)

Such a conglomerate of  $\gamma$  units will be denoted as a micelle. The  $\alpha$  and  $\beta$  units together will be soluble in solvents in which the  $A$  resin itself is soluble

the same time, however, the number of  $\beta$  units increases at the expense of the  $\alpha$  units, so that a condition more and more like that of  $P$  in Fig. 3 will be reached. This behaviour will counteract the positive factors for high elasticity according to van Dongen's formulas. The fact that some high elasticity has been observed with asphalts indicates that when  $\eta = 10^{11}$  to  $10^{13}$  poises the conditions are especially favourable. We shall return later to this subject of the high elasticity of asphalt and glass.

Let us now consider a hardening resin in the  $B$  stage. Reference to Table II. recalls the fact that, when the degree of polymerisation necessary for high elasticity has been reached, the resins are only partly soluble,

and Newtonian flow is no longer possible (at 60° C.). As has already been mentioned, these facts, and the relatively small decrease of the alcoholic extract compared to the large increase in elastic behaviour which is observed during the condensation process on the rolls, may be indications that at this stage large micelles are growing into each other to form a three-dimensional network throughout the mass. In Fig. 4c an element of such a network is represented. This net is principally different from that of Fig. 4b because of the fact that *most of the elements are held in their relative positions by primary bonds*. At room temperature  $\beta$  units are still present in the system. If such a *B* resin is heated until most of the secondary bonds between the  $\beta$  units are broken (the situation in Fig. 4c) *a network of  $\gamma$  units still remains which is capable of storing up a large amount of potential energy in its elements*.

The resin under consideration now shows a great resemblance to *Q* of Fig. 3, and if we accept this structure for a *B* resin, its high elasticity may be explained on the basis of formula (4) and (5). The fact that the elastic recovery is a *thermo-recovery* may be ascribed to the high viscosity of the  $\alpha$  and  $\beta$  units at room temperature, which prevents the deformed network from recovering its original shape.

Table II. shows that the content of  $\alpha$  and  $\beta$  units together is still about 25 to 65 per cent. In a resin of the phenol-formaldehyde type (and also of the glyptal type) the viscosity at 20° C. of the  $\alpha + \beta$  units present will be at least about 10<sup>6</sup> poises.<sup>22</sup> This very high value for the viscosity offers an explanation of the lack of recovery of the *B* resin at room temperature.

If the temperature is raised, the conditions for recovery become favourable, since the viscosity coefficient  $\eta$  of the "liquid" decreases by a factor of 10 for each 10 degrees increase in temperature.<sup>10</sup> Roughly speaking, the velocity of recovery therefore also increases by a factor of 10 for every 10 degrees increase in temperature. The value of  $\eta$  for the  $\alpha + \beta$  units at 120° C. appears to be about 10 poises,<sup>22</sup> so that the  $\alpha + \beta$  units at that temperature may be compared with a liquid like glycerol at room temperature.

According to a recent investigation of Derksen<sup>23</sup> a maximum of 50 per cent. of water can be taken up in the crystallites of gelatine, while up to 950 per cent. can be stored up around and between the crystallites. The high elasticity of such a gel as gelatine, not being thermo-elasticity, may probably be explained by the lower viscosity of the large amount of liquid (water in the case of gelatine) compared with the viscosity of the liquid in an isogel like a resin at room temperature.

Upon cooling a highly elastic *B* resin the  $\alpha$  units will be gradually transformed into  $\beta$  units again, and the situation *P* of Fig. 3 is more and more nearly reached, where high elasticity is no longer possible. The more such a body is cooled, the more truly elastic become the deformations due to the decrease in heat motion, and therefore in capacity to migrate, of the  $\beta$  molecules present.

The situation in the case of *resins in the C stage* may be represented

<sup>22</sup> This value can be found by extrapolation for a phenolformaldehyde resin of Novolak type (see Houwink, *loc. cit.*<sup>10</sup>, Fig. 30).

<sup>23</sup> J. C. Derksen, *Diss. Utrecht*, 1935.

by Fig. 4d, where only  $\gamma$  units are present which form (when the *Lockerstellen* are neglected) one large macromolecule. A "net element" has been drawn in this figure of the same shape as in Fig. 4c, but here surrounded only by  $\gamma$  units. The analogy with  $P$  in Fig. 3 is here obvious, and the impossibility of high elasticity is due to the same considerations.

An explanation of the high elasticity of *glass* may be sought on the basis of the foregoing discussion. In Table III, it will be seen that the high elasticity is especially observed at a viscosity corresponding to the transformation interval. During this interval  $\gamma$  units may be supposed to be present along with  $\alpha$  units (perhaps also  $\beta$  units), so that a structure of the type represented in Fig. 4c may be assumed. The question then arises as to whether or not high elasticity as in a  $B$  resin (200 to 240 per cent.) will be encountered, and may be answered by examining whether or not the necessary conditions for the storing up of elastic energy  $e_p$ , mentioned in section 1, are satisfied.

Keeping in mind the fact that high elasticity in glass was observed within a viscosity range of about  $10^{11}$  to  $10^{13}$  poises, that is to say, in the neighbourhood of the transformation interval (see § 2), one may immediately conclude that *no great quantity of energy can be stored up in the glass at that high temperature*. It must further be remembered that for a  $B$ -resin high elasticity was observed to be connected with the occurrence of quasi flow. For the resin this may indicate that strong net fragments have been formed with a high energy content compared with the value of  $3KT$ , and that these fragments can still be deformed under the influence of shearing stresses because they are partly separated to some extent by  $\alpha$  units. In the case of glass this viscosity indicates that the softening point is approaching, so that groups of molecules are formed which cohere with an energy content of about  $3KT$ .

The reason for this difference between a  $B$  resin and glass lies in the fact that, in the case of the resin, a *chemical reaction* is necessary to cause the formation of  $\gamma$  units from  $\alpha$  units, and it *results in a jump in energy content*, of the  $\gamma$  units compared with the  $\alpha$  units. In the case of glass, however, the transition  $\alpha \rightarrow \gamma$  is a more gradual process *without sudden change in energy*, and is much more nearly analogous to the gradual transition  $\alpha \rightarrow \beta$  in a non-hardening resin. This conception is supported by the work of Berger cited in the foregoing paper, where it is demonstrated in full that during the transformation interval there is no sudden change in volume, heat content or other quantities of state.

In the case of *asphalt* the observation of high elasticity at a viscosity of about  $10^{11}$  to  $10^{13}$  poises is an indication that, under these conditions, a network of the type of Fig. 4b is present which is able to store up a certain amount of potential energy. This network will contain about 20 to 30 per cent. of  $\gamma$  units (asphaltene micelles), and further probably chiefly  $\beta$  units. The observation that high elasticity is more pronounced with blown asphalts may perhaps be connected with their higher asphaltene content, which would result in a closer contact<sup>24</sup> of the asphaltene micelles. This supposition is confirmed by the fact that such blown bitumens exhibit no Newtonian flow. High elasticity phenomena of some hundred per cent., as are encountered in hardening resins, might be expected in the case of asphalts only if interlinks of high energy

<sup>24</sup> Compare F. J. Nellensteyn, *World Petroleum Congress*, 1933. Preprint 56.

content could be created between the asphaltene micelles, and if the petrolene content could be lowered below about 70 per cent.

It must be admitted that many points of the above discussion are still rather vague because of the lack of accurate experimental data and theoretical insight. Our only intention has been to make a preliminary attempt to show the accordance between the outstanding theory and the observations of elasticity. Very much more experimental work is necessary before the problems of this subject can be entirely solved.

### Summary.

1. A general description is given of the phenomena of high elasticity of matter. The relation is shown between the maximum amount of elastic energy which can be stored up in a material and the energy content of the bonds.

2. The results of certain experiments on high elastic behaviour of the above-mentioned materials are dealt with. The hardening resins are further studied in particular. A high elasticity of up to 240 per cent. can be observed for hardening resins at a high elasticity temperature of about 120°C., and the relation is shown between the conditions for this behaviour and the formation of insoluble, elastic, three-dimensional networks.

3. High elasticity can also be observed with materials like asphalts and glass but not to the same extent as with *B* resins. In the case of asphalts and glass it is only of the order of 10 to 20 per cent. For the materials described the possibility of high elasticity seems to be connected with a viscosity of the order of  $10^{11}$  to  $10^{12}$  poises (near the transformation interval).

4. Calculations are given to explain the changes of Young's modulus, yield value and strain at the yield value, when compact bodies are transformed into open net structures.

5. An attempt is made to give a rough explanation of the high elastic behaviour of asphalts, resins and glass on the basis of the energy content of their internal bonds with reference to the internal net theory developed.

Our sincere thanks are due to Dr. J. H. de Boer and J. R. J. van Dongen, of our Philips' Laboratories, for their critical assistance, and to Mrs. H. E. Teves-Aelv for the translation of the manuscript.

### GENERAL DISCUSSION.

**Professor H. Mark (Wien)** said: In connection with the interesting contribution of Dr. Houwink I want to refer also to the paper of Dr. de Boer. It seems to me very reasonable to try now to get quantitative results in the theoretical interpretation of the mechanical behaviour of synthetical resins. Our spatial models of the structure of these substances and our general knowledge of the intermolecular forces are already so well founded that it seems permissible to undertake such a task.

If one seeks to calculate quantitatively the modulus of elasticity of high polymeric substances which are built up from long carbon chains, I think one must take into account not only those effects which Dr. Houwink has discussed, but also the fact that the directions of the chemical main valence bonds are not rigid, but can be bent from their original direction, if one applies sufficient energy. From the theory of internal tension of ring molecules and from spectroscopic data one can estimate the amount of these energies. The following values are taken from a book of H. A. Stuart:—

Substance.	Energy to bend the Valence out of its Original Direction.		Distance of the Atoms.
	5°.	10°.	
HCN 	~ 200 Cal./Mol.	~ 800 Cal./Mol.	H — C = 1.08 Å.
C <sub>2</sub> H <sub>2</sub> 	~ 200 Cal./Mol.	~ 800 Cal./Mol.	H — C = 1.08 Å.
CO <sub>2</sub> 	~ 450 Cal./Mol.	~ 1750 Cal./Mol.	C — O = 1.15 Å.
CS <sub>2</sub> 	~ 300 Cal./Mol.	~ 1200 Cal./Mol.	C — S = 1.5 Å.

If one compares this with the energy, which is necessary to stress a chemical main valence bond in its own direction it is seen that the latter energy is much larger than the former.<sup>25</sup> Therefore one has to assume that at the start of the elastic stress the valences are first bent from their original direction and then are stressed themselves.

FIG. 1.

If we want to increase the distance between A and C (Fig. 1) by 10 per cent. we have the two possibilities: we can increase the angle  $\alpha$  by  $d\alpha$  and keep  $a$  constant or we can increase  $a$  by  $da$  and keep  $\alpha$  constant.

The distance between A and C is always given by

$$2b = 2a \sin \alpha.$$

The two possibilities of increasing it are

$$db = a \cos \alpha d\alpha$$

and

$$db = da \sin \alpha.$$

If we want to get the same relative increase, namely, 10 per cent we have to write

$$\frac{db}{b} = 0.1 = \frac{a \cos \alpha d\alpha}{a \sin \alpha} = \cotg \alpha d\alpha,$$

$$\frac{db}{b} = 0.1 = \frac{da \cdot \sin \alpha}{a \cdot \sin \alpha} = \frac{da}{a}.$$

Taking for  $\alpha$  and  $a$  the values, which hold for a carbon chain, we find

$$d\alpha \sim 8^\circ$$

and

$$da = 0.15 \text{ Å.}$$

In the first case we want between 1000 and 1500 cal./mol., in the second certainly more than 5 or 6000 to produce the same elongation  $db$ .

I tried some time ago to calculate the modulus of elasticity of the diamond from the well-known lattice of this substance or the assumption, that the valence directions are initially modified, and Professor Meyer has recently accomplished similar considerations. One gets the right order of magnitude, but cannot compare this result with the experiment

<sup>25</sup> To stress the C—H bond to the extent of  $0.1 \times 10^{-8}$  cm. one requires about 5000 cal./mol. and to stress the C=O bond in CO<sub>2</sub> for the same amount one needs more than 11,000 cal./mol.

because the modulus of the diamond is not measured in certain crystallographic directions.

I would like to add, that in the case of rubber-like elasticity a statistical effect has to be taken in account. This was first derived by Professor Meyer from the temperature-dependence of the elastic behaviour of rubber and was recently discussed in detail by Guth and myself. It is an effect which leads to very interesting results as to the behaviour of long chain molecules. To what extent it plays a rôle together with the other effects quoted by Dr. Houwink must be tested in every special case by careful measurements of the influence of temperature on the extension curve.

Finally very interesting considerations on the elasticity and plasticity of high polymeric substances were made by Dr. O. Kratky and discussed at the meeting of the Bunsengesellschaft in Berlin last spring. The results seem to be in good agreement with what Dr. Houwink has said.

**Professor E. K. Rideal** (*Cambridge*) said: Calculations of the tensile strength of a material involve the assumption of instantaneous or simultaneous withdrawal of two planes of atoms from one another and that each atom is linked to its opposite partner by one of two types of linkage, the covalent or the dispersive Van der Waals' type. It has been frequently pointed out that withdrawal of a covalent linked chain of atoms from the interior of the surface may take place instead of the breakage of a covalent link at the surface, if the former operation takes place more readily. It must also be observed that the material in a polymer is not fibrous as in cotton and in consequence of the flexibility of bent chains the mechanism of rupture may not be instantaneous or simultaneous over the total area of the specimen but one part of the extending and separating interface may stretch more than another.

**Professor K. H. Meyer** (*Genève*) said: Dr. Houwink has asked whether in my opinion rubber-like extensibility is always connected with the presence of long-chain molecules. The extensibility can have different origins. The elasticity of a steel spring is not connected with the presence of long molecules, and a similar mechanism might be found in other elastic materials. But in all homogeneous substances which show rubber-like elasticity, one could always establish the presence of long molecular chains, and I can very well imagine that chains are also the cause of elasticity in Houwink's substances. In the phenol formaldehyde condensation products the elasticity is observed only at a certain degree of polymerisation. We must assume that, at first, the phenols build up chains with the formaldehyde, e.g.,

It seems possible that the elasticity is due to this state, and that the cross linkages, which are formed in the subsequent phases of the polymerisation process inhibit the extensibility by formation of a solid tridimensional network.

**Dr. J. H. de Boer** (*Eindhoven*) said: Perhaps there may be added still one argument for the existence of *Lockerstellen* of the type indicated by Figs. 5a and 5b of Dr. Houwink's first paper. The dielectric behaviour of these condensation products supports this argument. This behaviour can be understood if little holes are assumed in which some electrolyte may wander to and from in the electric field. Now, from the paper of Dr. Houwink we see that such holes are very probable and that they may contain water of condensation and free OH-groups.

**Professor H. Staudinger** (*Freiburg i. Br.*) said: Very many elastic materials have a somewhat complicated structure, e.g., vulcanised rubber, factis and the elastic phenol-formaldehyde condensation products. In

order to get an insight into the relations between elasticity and molecular structure, simple compounds of high molecular weight ought first to be investigated (and particularly the polymeric homologous series of such substances). The investigation of a number of polymeric hydrocarbons (e.g., rubber (polyprenes), hydorrubber (polypranes), polyisobutylenes), has proved that pronounced elastic properties are possessed only by the products of highest molecular weight and are entirely absent in the case of hemicolloidal products. Therefore the high elasticity of these substances must depend on the fact that they are built up of large macromolecules. Since saturated aliphatic hydrocarbons can also be elastic it follows that, contrary to previous suggestions, the double bonds in the rubber molecules are not essential to an explanation of the elasticity. However, with these observations the general question of elasticity is not yet definitely cleared up. Hard tough eupolystyrene becomes elastic when heated to 120°-150° and furthermore also by the addition of small amounts of solvent.<sup>26</sup> According to this it is very likely that under suitable conditions all high molecular weight substances, which are built up of thread molecules, assume elastic properties.<sup>27</sup>

**Mr. N. J. L. Megson** (*Teddington*) said: Referring to the formation of "Lockerstellen," which are suggested as partly due to structural difficulties in the elimination of water between methylol and hydroxy groups: evidence supporting this idea is contained in the results quoted for the two types of phenolic resins employed. Cresylic acid, on account of its *m*-cresol content should give a resin with structure analogous to that of phenol resins, together with a high proportion of long chain molecules derived from the *p*-cresol content. The intrusion of these long chain derivatives between branches of the *m*-cresol resin may be an additional factor in preventing elimination of water, thereby increasing the tendency to formation of *Lockerstellen*. Experimentally, cresylic acid resins possess a tensile strength of 3.8 kg./mm.<sup>2</sup> instead of the theoretical value of 32 kg./mm.<sup>2</sup> which is a lower *proportional* value than that shown by phenol resins (7.8 kg./mm.<sup>2</sup> experimentally compared with the theoretical value > 39 kg./mm.<sup>2</sup>).

**Dr. L. C. Verman** (*Teddington*) said: In the course of the discussion, various points have been raised which indicate that the calculations of modulus of elasticity and tensile strength as presented in the paper may only be regarded as approximate. It is therefore not surprising to find that the calculated values are much higher than the experimental. It appears that probably too much stress has been laid on the existence of *Lockerstellen* and their influence in determining the mechanical properties of resinous materials, etc. It would be interesting, however, to demonstrate the existence of *Lockerstellen* directly in resinous materials and, if possible, to determine the extent of their influence. Methods of fatigue test commonly used in testing metals may prove useful in this connection.

**Dr. R. Houwink** (*Eindhoven*), said, in reply to Professor H. Mark: Dr. de Boer and I wish to express our sincere thanks for the very fundamental suggestions made. When considering polymers, built up from long carbon chains the bending phenomena pointed out by Professor Mark must, of course, be taken fully into account. In our opinion the situation with amorphous three-dimensional polymers in the C stage is, however, different, in so far that the conditions necessary for displacement of atoms A and C in regard to B will not be very favourable. In the ideal case (on which are based the theoretical calculations) A, B, and C are bound to their neighbours by means of primary bonds and, therefore, the possibility of bending the valences AB and BC out of their original direction will be materially decreased. *This is fundamentally different in the case of materials such as*

<sup>26</sup> H. Staudinger and H. Machemer, *Ber.*, 1931, **62**, 2922.

<sup>27</sup> Compare H. Staudinger, *Die hochmolekularen org. Verbindungen*, Verlag Springer, 1932, p. 122.

rubber, where the atoms A, B and C are bound to any other carbon atom of a neighbouring chain merely by means of readily deformable secondary bonds.

We nevertheless agree with Professor Mark to the extent that the effect he mentions should not be neglected in the calculation of mechanical properties. The only difficulty is that such a calculation would become extremely difficult. There is one point in our favour, namely, that by taking the bending effect into account, the theoretical values for the tensile strength would become still higher, because the energy necessary for the bending process must be added to the energy of stressing, calculated in de Boer's paper. As de Boer has calculated *minimum values* he has gone along safe lines. With regard to the theoretical value for the modulus of elasticity, this may indeed become lower if the bending effect should play an important rôle. From a scientific point of view it would be very interesting, therefore, if exact calculations, taking the bending effect into account, could be carried out.

It seems to me that the statistical effect (Joule effect as a consequence of changes in internal energy on deformation) in high-elastic substances, mentioned by Professor Mark, will not play an appreciable rôle in the experiments on three-dimensionally polymerised materials, described in my second paper. There are three separate groups of authors, namely (a) Meyer and Ferri,<sup>28</sup> (b) Wiegand and Snyder,<sup>29</sup> and (c) Hencky<sup>30</sup> from whose work one may take it that this Joule effect in rubber is not observed when it is stretched less than roughly 300 per cent. The first and second-named investigators find this limit to be 400 per cent. and 300 per cent. respectively. Hencky on purely theoretical grounds calculates it to be 270 per cent. As the elastic deformations described in my paper do not exceed 240 per cent., it seems therefore improbable that the *Abstoßungsdruck* of K. H. Meyer and co-workers<sup>31</sup> has to be taken into account in the case of resins, glass and asphalt. This seems to be the more true since the conditions for orientation in 3-dimensional materials seem to be much less favourable than in materials with long chains. Notwithstanding these arguments I agree with Professor Mark that an investigation on this subject would be extremely interesting.

With regard to the supposition of Professor Rideal that a withdrawal of some covalent linked chain from the surface of rupture may occur when such a chain is attached to other atoms by means of van der Waals forces, it may be said that this situation is for the greater part in agreement with the picture which has been postulated in the *Lockerstellen* theory for resins. In my opinion a withdrawal of irregular blocks (instead of chains in the case of amorphous three-dimensional polymers) may actually occur and, for this reason, it seems very probable to me that the mechanism of rupture will involve an uneven distribution of stress over the separating interface. It is also partly for this reason that the actual modulus of elasticity  $E$  may be expected to be some mean between  $E$  for the covalent bonds and  $E$  for the van der Waals bonds. As mentioned in my paper, the experimental value of about 1000 kg. mm.<sup>-2</sup> for  $E$  in liquid air is a strong argument for this conception, because it lies between the theoretical values of 11,000 kg. mm.<sup>-2</sup> for covalent bonds and  $> 45$  kg. mm.<sup>-2</sup> for van der Waals bonds.

With regard to the remarks of Professor K. H. Meyer related to the steel spring, I would like to say that the high-elasticity of such a spring is based on the same principles as used in Fig. 3 of my second paper. To Professor Meyer and Professor H. Staudinger together I should like to say that in the highly elastic resins described in my second paper the presence of long molecular chains is very improbable in the initial stage of

<sup>28</sup> K. H. Meyer et C. Ferri, *Helv. Chim. Act.*, 1935, **18**, 570.

<sup>29</sup> W. B. Wiegand and J. W. Snyder, *Trans. Inst. Rubb. Ind.*, 1934, **10**, 234.

<sup>30</sup> Hencky, *Trans. Am. Soc. Mech. Eng.*, 1933, **55**, 55-8-45.

<sup>31</sup> K. H. Meyer, G. von Susich and E. Valko, *Koll. Z.*, 1932, **59**, 208.

condensation as well as at the end stage. This has been pointed out in my book (*Phys. Eigenschaften und Feinbau von Natur- und Kunstharzen*, Leipzig, 1934). The best proof that the high-elasticity is not to be ascribed here to the presence of long chains seems to be that *no high-elasticity is observed with these resins so long as they are soluble*. On the contrary, the high-elasticity is only observed in a stage of condensation in which the resins are to a large extent insoluble.

I fully agree with Mr. N. J. L. Megson that the presence of *p*-cresol (and *o*-cresol) in the crysilyc acid resins will increase the tendency to formation of *Lockerstellen*. I do not believe, however, that the *p*-cresol resins will be present as long chains. If in the relatively short reaction time necessary to reach the B-stage in my experiments, the *p*-cresol formaldehyde molecules should have reached some appreciable magnitude (which in my opinion is very improbable) they might perhaps be present in a coiled-up form, but not as extended chains (see the foregoing answer).

To Mr. L. C. Verman I would like to say that the approximations made by Dr. de Boer in his calculations as to the strength of resins have always been carried out in such a way that he adopted the most unfavourable conditions. His theoretical values are therefore *minimum values*, and from this point of view there is no reason to say that too much attention has been paid to the *Lockerstellen*. Fatigue tests may be very important from a point of view of testing materials but, in my opinion, they do not seem very adequate in procuring insight into structural problems, because such tests are amenable only with great difficulty to mathematical treatment.

## INORGANIC SUBSTANCES WITH RUBBER-LIKE PROPERTIES.

By KURT H. MEYER (*Geneva*).

*Received 15th July, 1935.*

Two inorganic substances with elasticity similar to that of rubber are described in the literature of the subject, *viz.* elastic sulphur and poly-phosphonitrilic chloride. In this paper we shall deal with investigations of both.

It is common knowledge that sulphur heated to 170° becomes highly viscous; if then cooled, *e.g.*, by plunging into water, it yields an amorphous elastic product.

If threads of this amorphous product are stretched, they show a double refraction, and, as Trillat<sup>1</sup> has found, develop a fibre-diagram. With Go the author<sup>2</sup> has examined this diagram, and deduced from it the following arrangement of the sulphur atoms: long chains of sulphur atoms, linked by strong homoeopolar valences, are arranged parallel to the direction of stretching. Their special position in the elementary cell is shown in Fig. 1.

In a recent publication, B. E. Warren<sup>3</sup> has made it clear that common sulphur is made up of 8-atom rings. The molecular weight of the elastic form  $S_n$  is not known, but seems to be very high.

We know from earlier work that the melting of sulphur produces an equilibrium between the two forms, and this shifts, at higher temperatures, in favour of the chain-sulphur. About 1000 calories per gram atom S are consumed in the transformation of  $S_8$  into  $S_n$ .

<sup>1</sup> 1932 (4), 51, 248.

<sup>2</sup> *Helv. chim. act.*, 1934, 17, 108.

<sup>3</sup> *J. Chem. Physics*, 1935, 3, 6.

Endothermic reactions can only proceed if there is at the same time an increase in entropy—in other words, if the atoms, in the endothermic form, have more room to oscillate, that is to say, have a greater "phase-volume." During the process of transformation, however, there is no increase in volume, but, on the contrary, a slight decrease; this, therefore, can only be explained on the ground that the sulphur atoms in the chain are more mobile than those in the rings. In view of this, the chains must be flexible. This entirely agrees with our conception of the nature of elasticity, which has recently been published.<sup>4</sup>

Some light is thrown upon the kinetics and mechanism of the polymerisation and depolymerisation of sulphur  $S_8 \rightleftharpoons S_n$  by the following facts, some of which were already known, while others have been only lately observed by Sievers. Both polymerisation and depolymerisation are catalysed by light; this indicates that  $S_8$  molecules are split up by a quantum and then, in the manner of a chain reaction, unite with other sulphur rings, whereupon the product then produced becomes active, and is capable of splitting up other rings and attaching them to the rapidly-growing chain. Conversely, a completed chain in a metastable state may be expected to disintegrate rapidly as soon as activation takes place at any point.

If purified sulphur is heated in pyrex vessels, it remains a thin fluid up to  $172^\circ$ , or a few degrees higher if in the dark. Above that point, it changes quite suddenly into an orange-coloured, resinous substance, and during that process the temperature falls by about  $1^\circ$ . If now carefully cooled, the resinous substance quickly liquefies again, and, when it is re-heated, the transformation

into the resinous substance takes place at a lower temperature and more gradually. If this process is repeated, the transformation becomes more gradual every time, and all the phenomena of retardation disappear. The metastable fluid state, which is easily obtainable in virgin sulphur at  $170^\circ$ , can no longer be secured. The explanation, we think, is, that in the process of heating, active molecules, on which chains form very rapidly, appear only at relatively high temperatures; in the process of cooling, the chains break away, but leave nuclei which, on re-heating, quickly establish equilibrium (formation of chains).

The polymerisation of metastable virgin sulphur at  $170^\circ$  can also be initiated by the addition of a very small quantity of polymerised product or product in process of polymerisation.

If sulphur is heated to much higher temperatures (about  $300^\circ$ ), its viscosity decreases and it turns brown. If it is then cooled, the viscosity rises again, but not up to the maximum that is reached at a

FIG. 1.—Arrangement of atoms in the elastic sulphur.

<sup>4</sup> *Helv. chim. act.*, 1935, 18, 570.

temperature of  $200^{\circ}$ , on heating virgin sulphur. If cooled still further, it slowly liquefies; on heating thereafter, it quickly becomes viscous, but never acquires the high viscosity of heated "virgin" sulphur.

Hence it would seem that, at high temperatures, the long chains break up into a large number of shorter chains, which are more stable than the long chains of "virgin" sulphur. Possibly, in the process of cooling, they leave behind such a large number of nuclei that on re-heating a large number of short chains are formed instead of a small number of long ones.

The viscosity of highly viscous sulphur is greatly diminished, by addition of traces of halogen or of hydrogen-sulphide; at the same time, the amount of  $S_8$  in the equilibrated mixture becomes smaller. We think that shorter chains with Cl, Br, I or H at the ends are formed:

These phenomena show that the polymerisation of sulphur is to be regarded as similar to that of other reactions of polymerisation.

The second elastic substance is polyphosphonitrilic chloride, discovered by Stokes,<sup>5</sup> which is produced by heating various phosphonitrilic chlorides of low molecular weights, namely, the annular compounds:

Polyphosphonitrilic chloride is almost indistinguishable, externally, from slightly-vulcanised rubber. Under tension it develops a double retraction and yields a fibre diagram, as Pankow<sup>6</sup> has discovered. This diagram shows a fibre period of  $5.17 \text{ \AA}$ , and in the direction of the fibres a diagonal screw axis. The most probable arrangement of the P and N atoms is shown in Fig. 2, which is based upon the X-ray diagram, the diameters of the P and N atoms and the angles known from compounds such as  $\text{POCl}_3$  and  $\text{NH}_3$ .

Here again, like in sulphur or stretched rubber, long chains of primary valency are arranged parallel to the direction of tension. The space of one identity-period in the axis is occupied by two  $\text{PNCl}_2$  residues. When the tension is withdrawn, the interferences disappear. Cooling in the tense state causes the crystallised state to "freeze stiff," as in the case of rubber or fibrous sulphur.

We have also plotted the load-extension curve of this inorganic rubber. Phenomena of plastic flow are superposed on the phenomena of elastic deformation; on the whole, this curve resembles that of rubber. We have investigated them with reference to the temperature-tension curve of a stretched test piece, and the curve is also wholly analogous to that of rubber (Fig. 3).

<sup>5</sup> *J. Am. chem. Soc.*, 1895, **17**, 275; 1897, **19**, 782.

<sup>6</sup> *C. r. de la Soc. phys. et hist. nat. de Genève* (Juillet, 1935).

On heating, at a constant degree of deformation, the tension increases, and more than would be proportionate to the absolute temperature. The reason is that crystallised portions "melt" and also undergo tension. On cooling, the tension remains at first higher than in the process of heating and decreases proportionately to temperature; it gradually continues to decrease also at constant temperature. The substance enters at first into the amorphous "under-cooled, metastable state," and crystallisation and the restoration of the original degree of tension takes place only gradually.

Definite information as to the mechanism of contraction can be drawn from this temperature-tension curve. Contraction is produced, not by the action of attractive forces, but by the thermal agitation of

FIG. 2.—Probable arrangement of the P and N atoms in polyphosphonitrilic chloride.

FIG. 3.—Stress-temperature curve of  $(N)PCl_2$  at 200 per cent. extension.

the links of the flexible chains, which tends to produce the statistically preferred condition in which the chains are completely *disorientated*, in comparison with the less probable *orientated* arrangement.\*

We are not as yet in a position to make any statement on the kinetics and the equilibrium of the polymerisation of  $(PCl_2N)_n$ . Henmi has found, however, that the reaction is reversible: depolymerisation sets in slowly at low temperatures under the influence of specific chemicals, such as dioxane. A mixture of the phosphonitrilic chlorides of lower molecular weights is thus obtained.

The same considerations apply here as in the case of sulphur. If

\* Cf. the theory of elasticity of rubber given by Meyer, Valko and Ferri, *Kolloid. Z.*, 1932, **59**, 208; *Helv. Chim. acta*, 1935, **18**, 570.

endothermic polymerisation is to be possible, the atoms or groups of atoms in the polymeric product must have a greater phase-volume—*i.e.*, greater mobility—than in the rigid annular trimer or tetramer. Hence the chains must be flexible.

It will be seen that there are strong analogies between the two inorganic and highly polymeric substances and the organic polymers, both in the morphological arrangement of the atoms and in the manner of their polymerisation.

### GENERAL DISCUSSION

**Dr. R. Houwink** (*Eindhoven*) said: Is there an explanation of the recent observations of Sakurada and Erbring<sup>7</sup> on the change in tensile strength of stretched elastic sulphur threads with time. If the observations of these authors are corrected so that the tensile strength is calculated on the actual area during the test, it is, *e.g.*, found for a sulphur, prepared at 300° C., that the strength firstly decreases within two days from 720 to 282 kg. mm.<sup>-2</sup>, then it increases within four days to 1160 kg. mm.<sup>-2</sup> again, after which period it starts to decrease steadily as a consequence of the transition  $S_n \rightarrow S_8$ . If the rise from 282 to 1160 kg. mm.<sup>-2</sup> could be ascribed to an increase of the chains in the weak rubbery mass, to what cause may then the initial decrease be ascribed?

**Professor K. H. Meyer** (*Genève*), in reply to a question of Dr. Katz suggesting that there is a close connection between extensibility and the phenomenon of crystallisation on stretching (Katz-effect): One can easily understand that crystallisation occurs only, and only can occur, if the chains are built up in a regular way, like sulphur chains or natural rubber chains. If the chains are irregular (as in some natural protein chains, *e.g.*, the elastic ligament (*ligamentum nuchae*) or chains of so-called synthetic rubber, which is a very irregular and branched hydrocarbon), then we observe *extensibility*, but no *crystallisation*.

One can prevent rubber from crystallising by vulcanisation with a sufficient quantity of sulphur, so as to make the chains irregular.<sup>8</sup>

Referring to the theory of Mack,<sup>9</sup> who explains the contraction of rubber by forces of attraction which are saturated during contraction, I say most definitely, that this theory is in contradiction with the important phenomenon of the Gough-Joule-effect and therefore cannot be seriously taken into account. A saturation of forces or "condensation" would involve *evolution* of heat during contraction, while *absorption* of heat is observed.

As to the form of the molecule of sulphur in the liquid state, I can only say that the enormous rise in viscosity during production of the elastic form clearly indicates a polymerisation in the molten state.

Mr. Houwink speaks of the peculiar behaviour of freshly prepared elastic sulphur: the tensile strength first rises, and then falls. There are certainly several reactions, which by superposition can cause maxima or minima. Elastic substances, when heated and cooled, undergo a change in the molecular arrangement of the chains, a sort of partial "crystallisation," by which the solubility is augmented. This fact is well known with rubber, which shows different load-extension curves when it has been previously heated or when kept for some time at ordinary temperature. On this phenomenon is superposed, in the case of sulphur the depolymerisation, which diminishes the tensile strength.

## KINETICS OF RING-FORMATION AND POLYMERISATION IN SOLUTION.

By G. SALOMON.

(Received 9th August, 1935.)

In a series of experiments carried out by H. Freundlich<sup>1</sup> and his co-workers, the kinetics of the reaction

were investigated by measuring the increase of the halogen ion concentration, and the reaction was found to be strictly of the first order. The velocity of the reaction was not influenced catalytically by the presence of neutral salts, and impurities in the starting material were inactive. In aqueous and aqueous-alcoholic solution, it was necessary to use excess alkali, but this was merely to neutralise the halogen acid set free; apart from this, the reaction velocity was, within wide limits, independent of the  $(OH^-)$  concentration. The reaction also takes place in anhydrous organic solvents, but with a much smaller velocity.

Fig. 1 shows what great differences were observed by Freundlich and his co-workers in the velocity of formation of various rings. The 5-ring is formed 100,000 times quicker than the 4-ring. At first there was no theoretical explanation for this extremely small tendency of formation of the 4-ring; Ruzicka<sup>2</sup> had

found similar results in synthetical experiments, and he recognised a general regularity in intramolecular ring closures. The 4-membered ring is very easily formed by a bimolecular reaction, and Ruzicka attributed the very small tendency to formation in the intramolecular reaction to the infrequency with which the ends of the molecule meet, corresponding of course to the higher energy of formation of such strained rings. Actually, however, the circumstances are even more complicated than this, but the theory has been of great value to us<sup>2</sup> and the subdivision

<sup>3</sup> Freundlich and Salomon, *Ber.*, 1933, 66, 355.

into energy- and statistical-factors <sup>4</sup> soon allowed us to recognise a number of regularities.

Some time ago, Ziegler <sup>5</sup> and his co-workers were successful in synthesising many-membered ring systems in dilute solution, and these experiments seemed to us to be a promising basis for the investigation of the reaction kinetics of the formation of cyclic imines with a large number of ring members. Experiments carried out in the laboratory of L. Ruzicka and in collaboration with K. E. Meyer soon led to this goal. As shown in Fig. 1, the ring closure to a many-membered ring in aqueous-alcoholic solution proceeds 50 to 100 times more slowly than the formation of the 4-ring in aqueous solution, and thus differences are known of ring closures under similar conditions which vary in the ratio of 1 : 5·10<sup>6</sup>, depending on the length of the chain. Greater differences than these are recognised when comparing relative rates of formation in organic solvents, and the following figures will afford an example of this.

The period of half-change in the formation of a 5-ring in water from the corresponding bromamine is, at 25°, about one second; in toluene, a few minutes. At the same temperature, and in aqueous alcoholic solution, the half period of formation of a 14-ring is two months, and in toluene thirty-three years. In other words, the synthesis of the higher ring systems must be carried out at a higher temperature.

In contrast to the intramolecular ring closure reaction, the intermolecular polymerisation

is largely independent of the chain length; it is, however, influenced by the solvent, and this circumstance allows us to divide the influence of the solvent into inter- and intra-molecular factors, and to see the specific relation between the ring closure and the solvent. Naturally, the reaction velocity constants of the intra- and inter-molecular reactions are not comparable on account of the difference in the dimensions. On the other hand, the dependence of both reactions on temperature is given by the Arrhenius' equation, and by suitable division of the factors independent of temperature, it was possible to obtain comparable values. This comparison was carried out in the following way.

### Theory of Irreversible Ring Closure Reactions.

It is convenient to divide the course of the reaction into three phases:

1. The two ends of the molecule capable of reacting, in our case, halogen alkyl and alkyl amine are moved by thermal impacts of the surrounding molecules, this movement being defined by the links in the carbon chain and the valency angle. There is a definite probability that the ends of the molecule will approach within a distance  $r$ , the sphere of molecular activity.

2. The molecules attract one another, and form an intermolecular compound. This compound has a definite life period, and can either revert to the normal open chain compound or it can undergo the third phase of the reaction which is.

3. A thermal reaction resulting in ring formation.

<sup>4</sup> Cf. Hückel, *Theoretische Grundlagen der organ. Chemie*.

<sup>5</sup> Ziegler, Eberle and Ohlinger, *Ann.* 1933, **504**, 94.

Corresponding to this idea, we can formulate the Arrhenius' equation thus

$$k_1(\text{sec}^{-1}) = Z_1 \cdot e^{-\frac{E_1}{RT}} = P_1 \cdot Z'_1 \cdot e^{-\frac{E_1}{RT}},$$

$Z_1$  is a value calculated from the temperature function of the reaction velocity and  $Z'_1$  corresponds to the real reaction (phase 3), whilst  $P_1$  represents the probability of the first two phases.

We shall next consider the essential reaction, that is the case when  $P_1 = 1$  and  $Z_1 = Z'_1$ . The velocity of the reaction is determined by formation of halogen ions, or in general by the transition of halogen atoms from inside, to outside, the sphere of action.<sup>6</sup> The mechanism of the reaction is analogous to numerous bimolecular reactions between halogen alkyl and alkyl amine, but it is also related to inorganic reactions such as the transformation of purpureo-chromium chloride, to roseo-chromium chloride.<sup>6</sup> This reaction, the separation of a covalent link is an endothermic reaction, and therefore requires an appreciable energy of activation. Recently, M. Polanyi<sup>7</sup> and his co-workers have given a general scheme for ionogenic reactions. The theoretical calculations of the activation energy of such reactions agree well with the experimental values of 20 to 25 K-Cal. On the other hand, in the formation of 5-6 membered ring systems, generally a smaller energy of about 12 to 20 K-Cal. is found. The latter value is, however, also valid for the analogous bimolecular reaction. A reduction of the activation energy of this reaction is easily explained by the action of the amino group. The halogen ion will, in formation, be attracted by the amino group and the work required for the removal will, therefore, be diminished.

The factor independent of temperature,  $Z_1$ , has the dimensions of a frequency. According to Polanyi and Wigner,<sup>8</sup> this signifies in large organic molecules the frequency with which the atom or atomic group vibrates about a definite bond. On account of the connection between atom vibration and the Raman and infra-red spectra, this factor must have the value  $5 \times 10^{12} - 5 \times 10^{13} \text{ sec}^{-1}$ . According to this theory, therefore, the thermal decomposition of organic molecules is a pre-dissociation phenomenon.

As Table I shows, the theoretical value of  $Z$  was obtained in four very different types of ring closure. Other ring closures in aqueous solution (Fig. 3) show values which are smaller by several (1 to 3) powers of ten, but these deviations are easily explained by the closer statistical argument which follows. On the other hand the factor independent of temperature, is found, in organic solvents, to have a value which is  $10^5$  to  $10^7$  times too small. Since, on this account the intermolecular reaction also proceeds slowly in organic solvents, the solvent obviously influences the reaction mechanism. On account of the good agreement between the theoretical and experimental values for  $Z$  in Table I., it was clear, that water was the natural solvent for such ionogenic reactions and a specific explanation should be sought for the anomalies in organic solvents.

An increase in the value of  $Z'$  occurs only in the case of the ring closure of bromo-ethylamine (cf. Table I.), in which the molecule consists of only three atomic groups in contact one with another. This indicates certain inner degrees of freedom, and therefore the transference of energy

is favoured. In the following we shall discuss how far the differences between  $Z$  and  $10^{13}$  are caused by the probability of the first two phases.

It is important to define these probabilities. The first phase includes the change of the shape of molecules, which may be influenced by the chain length and may be different in various solvents. The second phase, which brings into question the life period of the intramolecular compound, may vary with the experimental conditions, *e.g.* with variation of the dielectric constant of the solvent and its hydrostatic pressure. In contrast, the third phase, the real reaction, should be affected only by the predissociation phenomenon; it is defined by the potential surfaces of the molecule. As the probability as to the first or second phase will be varied in our experiments, we shall discuss in this paper the *a priori* probability of these two phases.

If the active ends of the molecule approach to within the distance  $r$ , then the mutual attraction of the two groups will overcome the thermal forces. If we describe this spatial position as the "Ring Position," and all other possible forms as the "Chain Position," then we arrive at the equilibrium

and the definition may be given

$$P_1^\alpha = \frac{\text{Number of Molecules in the Ring Position}}{\text{Total number of Molecules}}.$$

Thus when  $P_1^\alpha = 1$ , all molecules are at any time in the ring position. On the other hand when  $P_1^\alpha = 0$ , it indicates that the ends of the molecule never approach to within the distance  $r$ . Let the average most probable distance of the molecule ends (in the normal position of the chain) be  $R$ . Then the value of  $P_1^\alpha$  is determined by the ratio  $r : R$  and the number of the possible transformations from the normal position to the ring position.

$R$  certainly increases with increasing length of the carbon chain. By considerations based on the study of models it is seen that the value

of  $R$  increases very rapidly, and the ratio of  $r : R$  becomes progressively smaller and finally reaches the limiting value of zero. This would lead one to think that there would be great differences in the ease of formation of the many membered rings, for instance between the 15- and 17-ring, and between the 30- or 32-ring. Ziegler's experiments have shown that this is not the case, and he has already pointed out the contradiction between experiment and theories based on models. The reason of the contradiction is probably as follows.

Long chain molecules are in constant Brownian movement,<sup>9</sup> and to this may be ascribed the magnification of the Eötvös constant in the case of the higher fatty acids.<sup>10</sup> Solutions of long chain compounds show for this reason, large anomalies in their osmotic behaviour.<sup>11</sup> It appears, therefore, that we should also ascribe to short chains a certain inner Brownian movement, and the vibration of the individual members of the chain one against the other renders the completely closed and the fully extended form equally improbable. Entropy considerations<sup>12</sup> indicate the half-closed form as the most probable, and if this is the case, then the introduction of another member into the carbon chain will increase the average distance  $R$  between the ends of the chain only by a small quantity, and  $R$  will tend to reach a limiting value.

The probability of ring closure will be governed by the condition of the valency angle, as the chain might frequently be in the necessary spatial position for ring closure, which can only occur if the position of the valency angle is correct. This "steric hindrance" of the valency angle distinguishes the 5-membered ring from all the others. The movement of the 5-membered chain takes place chiefly in a plane, and the three possible plane configurations predominate.

These three forms may be mutually converted, one into the other, or into the ring position, which is a contrast to the many spatial forms of the 6-, 7-, 8-membered chains. In longer chains this factor is of little importance as, on account of the great number of degrees of freedom, many of the spatial forms can be converted into the ring form.

Formerly it was assumed that all geometrical isomers were equally probable, but the Raman spectra of 3-, 4-, and 5-membered chains points

to the existence of at least two favoured forms.<sup>13</sup> Interatomic forces cause a limitation of the freedom of rotation<sup>14</sup> and individual geometric forms are favoured. According to Kohlrausch no characteristic Raman line for the ring configuration could be observed, as it is obviously hindered on statistical grounds, and the results of kinetic investigations are in harmony with this conclusion. For the 5-membered ring  $0.03 > P_1^a \leq 0.01$ . According to Fig. 2, however, every third molecule should be in the ring position, i.e.  $P_1^a = 0.3$ , and according to this the 5-ring occurs 10 to 30 times more seldom than would be expected on purely statistical grounds.

The first kinetic problem with which we have to deal is to prove qualitative agreement with the theory of the diminishing value of  $Z$  with increasing length of chain. It might be considered that only a few ring systems are what might be called "normal." What statistical circumstances would be met with in the strained 3- and 4-membered rings cannot be predicted, but even rings with a medium number of members—9 to 14—are anomalous. According to Ruggli,<sup>15</sup> J. v. Braun,<sup>16</sup> Ruzicka,<sup>17</sup> and Ziegler,<sup>5</sup> they are certainly difficult to form and Carothers<sup>18</sup> showed that they are extremely unstable when formed. Here we probably have the steric hindrance of the valency angle together with the hypothetical steric hindrance of the molecular structure itself.<sup>19</sup> These factors must therefore be added to the already complicated statistical circumstances.

Before discussing experimental results, the general influence of solvents on the speed of reaction should be referred to. Inter- and intra-molecular reactions result in the formation of molecular compounds in which the reactions finally occur.

The phase of the reactions which leads to this molecular compound is the only one affected by the difference in dimensions. Opposed to the simple ionogenic theory there is the additional restriction in both the complexes of the action of the amino group. In the sense of the theory of Polanyi and Wigner, no more than the energy with the frequency of  $10^{13}$  is necessary to overcome the C—Br linkage, but at the same time it must fulfil any restrictions there may be between  $^{20} \text{CH}_2\text{Br-solvent-NH}_2 \cdot \text{CH}_2 \text{---}$ . On account of this simultaneity the life period of the molecular compound will be real. The reaction consists, as it were, of a series of equilibria, thus:

<sup>13</sup> K. F. W. Kohlrausch, *Z. physik. Chem. B.*, 1932, **18**, 61. K. F. W. Kohlrausch and Köppel, *ibid.*, 1934, **26**, 209. *M.* 1935, **65**, 185.

<sup>14</sup> Eucken and Weigert, *Z. physik. Chem. B.*, 1934, **23**, 265.

<sup>15</sup> Ruggli, *Ann.*, 1912, **392**, 92; *Ann.*, 1913, **399**, 175.

<sup>16</sup> J. v. Braun, *Ber.*, 1906, **39**, 4110.

<sup>17</sup> *J. Am. Chem. Soc.*, 1929-1935; cf. J. v. Braun and co-workers, *Ber.*, 1924,

57, 185.

<sup>18</sup> M. Stoll and G. Stoll-Comte, *Helv.*, 1930, **13**, 1185.

<sup>20</sup> H. Eyring, *J. Chem. Physics*, 1935, **3**, 107.

Actually, the life period of the molecular compound in water is long. Only the equilibrium I (the steric factor) and III (activation energy) will then determine the velocity. In pure organic solvents on the other hand, the speed of reaction diminishes in the series nitrobenzene, acetophenone, benzyl alcohol, methyl alcohol, halogenated hydrocarbons, benzene, xylene, decalin. This series is in agreement with that which has been found for similar bimolecular reactions.<sup>21</sup>

There seems therefore to be a connection between the hindrance of the reaction, the ionisation process and the dielectric constant of the solvent, but this assumption is not sufficient. There is a non-ionic reaction which is slowed by the solvent, namely the association of free radicals,<sup>22</sup>  $2(\text{C}_6\text{H}_5)_3\text{C}\cdot \rightarrow (\text{C}_6\text{H}_5)_3\text{C}:\text{C}:\text{C}:(\text{C}_6\text{H}_5)_3$ . There exists, according to Ziegler, a relationship between radical formation and spatial packing.<sup>23</sup> If the radical has a high density, then the work of the association must be performed against the solvent, and the association will, therefore be hindered. Correspondingly in the amine reaction the molecular compound has perhaps a favourable spatial packing in polar solvents, and therefore the life period is increased. With increasing symmetry of solvent, the molecular compound finally reaches its normal life period, which consequently determines the rate of the reaction. The fact, therefore, of the solubility in organic solvents of the imine salts, which closely resemble the molecular compounds, is in some degree related to the speed of the reaction.<sup>24, 25</sup> To separate the influence of the solvent from the geometric factor  $P_1^a$ , we use a second probability factor,  $P_1^b$ , which is defined as follows:

$$P_1^b = \frac{\text{Number of non-activated molecules in the molecular compound}}{\text{Number of molecules in the ring position}}$$

and in aqueous solution  $P_1^b$  is 1.

For the intermolecular reaction we have the Arrhenius' equation

$$K_2 (\text{sec}^{-1} \text{ mol. } L^{-1}) = Z_2' e^{-\frac{E_2}{RT}} = P_2 \cdot Z_2' \cdot e^{-\frac{E_2}{RT}},$$

$Z_2'$  gives directly the frequency of collisions. The value of  $Z_2'$  depends on the mass and radius of the molecule, and is of the order of magnitude of  $10^{11}$  ( $\text{sec}^{-1} \text{ mol. } L^{-1}$ ). A certain correction is necessary for the viscosity of the solvent, but this does not affect the order of magnitude of  $Z$ . The probability factor  $P_2$  can again be divided into two components, the geometric factor and the influence of solvent  $P_2^a$  and  $P_2^b$  respectively.  $P_2^b$  may be defined as follows:

$$P_2^b = \frac{\text{Number of non-activated molecules in the molar compound}}{\text{Number of collisions}}$$

The two values of  $P^b$  make it possible to compare the influence of the solvent. The geometric structure of the chain plays scarcely

<sup>21</sup> Moelwyn-Hughes, *The Kinetics of Reactions in Solution*, Oxford, 1933.

<sup>22</sup> The hindrance of the reaction is calculated according to the measurements of Ziegler and co-workers, *Ann.*, 1929, 473, 163; 1933, 504, 131.

<sup>23</sup> *Trans. Faraday Soc.*, 1934, 30, 10.

<sup>24</sup> In this connection it would be essential to know the behaviour of the bimolecular reaction in water. This had not hitherto been investigated on account of the slight solubility of the halogen alkyls in water. For this investigation, the reaction  $\text{R}_2\text{N} + \text{Cl} \cdot \text{CH}_2 \cdot \text{CH}_2 \cdot \text{CH}_2 \cdot \text{NH}_2 \rightarrow \text{R}_2\text{N} \cdot \text{CH}_2 \cdot \text{CH}_2 \cdot \text{CH}_2 \cdot \text{NH}_2$  would be especially suitable, since the formation of 4-membered rings proceeds very slowly between 0° and 36°.

<sup>25</sup> Cf. Soper and Williams, *Trans. Chem. Soc.*, 1931, 2291.

any role in the bimolecular reaction, and as a matter of fact it is found that in a number of bimolecular reactions the length of the chain is without effect.<sup>26</sup> If, however, anomalies should appear, then we must consider that the extended chain form, in which the active groups are available from all sides, favours polymerisation, which is the direct opposite of the conditions for ring closure. In general the assumption that  $P_2^\infty \cong 1$  is sufficient.

### Shape of Chain Molecules and Solvent.

The statistical proportions encountered in the formation of imines are shown in Fig. 3.<sup>27</sup> The *a priori* probabilities for ring closure in water

FIG. 3.

— Solvent: Water.  
 - - - 30 per cent. isopropyl alcohol.  
 . . . Xylene.

the dissolved molecule will naturally favour the form with the smallest energy content, *i.e.* that form which presents the smallest surface area to the solvent. This means the ring position. In capillary active solvents, on the other hand, the surface forces are small in comparison with  $kT$ , and here the true statistical ratio is obtained. In xylene the correct sequence is found, and it behaves here with the relative ease of formation for the 6 : 7-rings of 10 : 1.

<sup>26</sup> Moelwyn-Hughes, *loc. cit.*, <sup>21</sup>, p. 91.

<sup>27</sup> The measurements for the 3-6 membered rings are largely drawn from the work of Freundlich, and are fully discussed in *Helv.*, 1933, 16, 1361. Exact measurements for the 7-ring in water, *Helv.*, 1934, 17, 851. The individual data for all other measurements are unpublished.

Now, are the surface forces between brom-hexyl-amine and water sufficient to bring about the kinetic anomalies observed? Langmuir<sup>28</sup> has shown how such differences of energy between the molecular forms can be calculated. He applied the known data of surface chemistry to the solution of the problem, and calculated the surface forces between water and a monocarboxylic acid in the cylindrical and the spherical form, and found the values shown in Table II.

TABLE II.

Acid.	Energy in ergs $\times 10^{-14}$ Cylinder.	Sphere.	$\lambda$ .	$P_A$ .
$C_3H_7COOH$	46	40	6	4.5
$C_{14}H_{29}COOH$	208	139	69	$3 \times 10^7$

The energy difference  $\lambda$  determines the ratio of the *a priori* probabilities of the two forms:  $P_A = e^{-\lambda/kT}$ , at ordinary temperatures  $kT$  amounts to  $4 \times 10^{-14}$  erg. Whilst with butyric acid the spherical form prevails over the cylindrical form only by 5:1, in palmitic acid the molecules are entirely in the cylindrical form. For an acid  $C_nCOOH$ ,  $\lambda \approx 15$  to  $25 \times 10^{-14}$  erg per molecule, which gives the corresponding value of  $P_A$  as  $10^{-1.6}$  to  $10^{-2.7}$ . As Fig. 3 shows, the probability of the formation of a 7-ring in water becomes  $10^3$  to  $10^4$  times larger. Thus with the help of this very crude comparison with the carboxylic acids, we reach the correct order of magnitude in the effects sought for.

For the exact application of Langmuir's method to the halogen-alkylamines, a great deal of physical data are lacking. Moreover, although the ring position considered here is similar to the spherical position of Langmuir, it is not identical with it. Correct orders of magnitude can be obtained, however, by comparing the compounds

TABLE III—SOLUBILITY IN MOLES PER LITRE AT ROOM TEMPERATURE.

$n$ .	$H-(CH_2)_nCOOH$ in Water.	$Br-(CH_2)_nNH_2$ in Water.	$Br-(CH_2)_nNH_2$ in 10 Per Cent. Iso- propyl Alcohol.
4	0.3	—	—
5	0.084	0.8	—
6	0.016	0.004	$2 \times 10^{-2}$
8	$7 \times 10^{-4}$	—	—
11	—	$< 1 \cdot 10^{-8}$	0.003
13	$\sim 5 \cdot 10^{-7}$	$< 1 \cdot 10^{-7}$	0.001
16	—	$< 1 \cdot 10^{-8}$	$< 0.001$

that of the  $CH_2Br$  group is larger than that of the  $CH_3$  group. Now according to Langmuir,<sup>29</sup> there exists a close relationship between solubility and capillarity, and, if the comparison is correct, the solubility of the alkylamines must be of the correct order of magnitude.

The fact is that the solubilities of the halogen alkylamines up to  $C_8$  are considerably larger than those of the corresponding carboxylic acids,

<sup>28</sup> *Colloid Chemistry*, by S. Alexander, New York, 1926.

<sup>29</sup> *Colloid Symposium*, III., 1925.

but in the transition from  $C_5$  to  $C_6$  the solubility sinks to a fourth in the carboxylic acids, whilst with the halogen alkylamines it falls to 1/200th of its value. The higher alkylamines have a very much smaller solubility, even in 10 per cent. isopropyl alcohol. This rather sudden change of solubility is simultaneous with the occurrence of the anomalous behaviour observed, and with the preponderance of the spherical form of the molecule. One may, therefore, suppose that the phenomena are related. In contrast to the carboxylic acids the halogenated amines can change into an inner molecular compound

In this molecular compound the actions of the hydrophilic groups are gradually mutually saturated, and in consequence of this, the action of the hydrophobic groups becomes stronger and the compound becomes insoluble in water. As long as the solvent has only a small effect on the molecular structure, the open chain form will remain in water, but if the spherical form is enforced by the solvent, then the more sparingly soluble molecular compound is formed.

If we take, on the one hand, the *a priori* probabilities found in benzene and xylene for the 6:7-ring = 10:1, and on the other hand, the observed solubilities, then the following values are probable (Table IV.).

TABLE IV.

Ring.	$Z_1 \text{ sec.}^{-1}$ .	$P_1^a$ .	$\lambda \cdot 10^{14}$ Erg Per Molecule.	$P_\lambda$ .	$P_1^a$ , Corrected.	Relative Frequency of the Ring Position.
5	$1.0 \cdot 10^{12}$	0.03	5	3.5	0.01	250
6	$2.5 \cdot 10^{11}$	0.005	10	10	0.0004	10
7	$2.5 \cdot 10^{13}$	0.5	40	25,000	0.00004	1

As can be seen it is necessary to make only relatively small proportional corrections for the 5- and the 6-ring to make the differences of the *a priori* probabilities appear six times larger. The assumption of a rather sudden increase in the value of  $\lambda$  for the 7-ring depends only on the observed insolubility, and this assumption was successfully proved with the aid of a kinetic method.

It is well known that the addition of a small quantity of a capillary active substance lowers the surface tension of water in a very characteristic manner, and this phenomenon depends on a change in the structure of the surface. Now, if there is a relation between the capillary activity of a solvent and the shape of molecules, then a change in the capillarity of the solution (not the surface) must influence not only the shape but also the *a priori* probability of reaction. The larger the value of  $\lambda$ , the larger this effect must be, and this is, as a matter of fact, the case.

The addition of only 10 per cent. isopropyl alcohol is sufficient to

lower the rapidity of formation of a 6-ring nearly by half, and with 30 per cent. alcohol the velocity is only a fourth of the velocity in water. After this, the addition of larger quantities of alcohol results in smaller decreases of velocity, until in 90 per cent. alcohol the value is one-tenth of that in water.

Thus the experimental values determined correspond with the calculated values of the *a priori* probability determined in Table IV. The good agreement of the figures is of course accidental. Effects of an entirely different order of magnitude are encountered in the formation of the 7-ring; here the addition of 10 per cent. alcohol is sufficient to reduce the *a priori* probability more than a thousand times; this becomes apparent by a decrease of  $\Delta H$  of about 3.6. Correspondingly the solubility is very much increased. Consequently the reaction in 30 per cent. alcohol is only twice as slow. Unfortunately bromohexylamine is very

difficultly accessible and the experiments in this direction could not be continued, but the foregoing experiments are sufficient to indicate the relations between shape of molecules, solubility and the velocity of reaction.

FIG. 4.

The energy of activation of the reaction is also closely bound up with the insolubility. Whilst the value of  $E$  remains constant in the formation of the 6-ring in water and in aqueous alcohol, it falls in the formation of the 7-ring about 4 K-Cal. The formation of the 7-ring from the bromamine in aqueous alcohol requires only 2 K-Cal more energy than the formation of the 6-ring in this solvent. This latter difference also obtains in benzene and is probably closely connected with the steric hindrance and the structure of the molecule. According to Polanyi, the larger the ionic radius of the halogen ion (in the nascent state), the larger will be the work of separation. The somewhat sudden increase in the energy of activation in water depends also on the formation of a hydrated sheath on the amino group. Freundlich<sup>30</sup> and his co-workers have found that certain ring closure reactions proceed not only in organic solvents but also in charcoal, with an activation energy of 4 to 5 K-Cal. less.

The exact investigation of the temperature coefficients of these reactions shows how inaccurate conclusions drawn solely from the velocity constants can be. The small rate of formation of the 7-ring (Fig. 1) in water is due to the large energy of activation, and in organic solvents to the infrequency with which the ends of the molecule approach each other. Similar circumstances obtain in the case of the formation of the 17-ring in aqueous alcohol solution and xylene. Generally the organic solvent favours a smaller activation energy and this would *ceteris paribus* cause a quicker reaction. But on the other hand the solvent is unfavourable to the value of  $Z$ , so that the final result is a diminished reaction velocity. In Table VI. a few examples of the influence of solvent are collected.

If the energy differences between the  $\text{C}_6$  chain and water are small, then the diminution of the value of  $H + \log Z$  in organic solvents shown in Table VI. can certainly not only be explained by capillary

<sup>30</sup> Freundlich and Juliusburger, *Z. physik. Chem. A.*, 1930, **146**, 321. Freundlich and Salomon, *Z. physik. Chem. A.*, 1933, **166**, 179.

chemical effects. For this a value of  $\lambda = 30$  to  $40 \times 10^{-14}$  erg per molecule would be necessary and this can in no wise be expected according to Tables I. and III. This consideration is naturally valid only for small chains. In long chains such as  $C_{16}$ ,  $\lambda$  may be greater than  $kT$  in alcohol and in nitrobenzol. In Table VI. the general effect of the solvents on  $P_1^\beta$  is set out and it may be compared with a few values of  $P_2^\beta$  for similar bimolecular reactions,<sup>21</sup> whereby the impression is obtained that the hindrance by the solvent is even greater in bimolecular reactions. If the intra- and inter-molecular compounds have equal life periods, the ring closure reaction is favoured. In these the energy of the whole molecule can overcome the C-Br link, whilst in bimolecular reactions only the atomic vibration in the halogen-alkyl molecule is active. The differences between  $P_1^\beta$  and  $P_2^\beta$  confirms that the life period of the molecular compound is diminished in organic solvents.

If we consider that to a first approximation the general solvent influence on the factor  $P_1^\beta$  is independent of the length of the chain, then the influence of the solvent can be completely taken into account. By com-

TABLE VII.

Ring.	5.	6.	7.	14/17.

Relative probability	$1.5 \times 10^4$	$5 \times 10^4$	$5 \times 10^5$	$\sim 1$

paring the theoretical results of Table IV. with the experimental results of Table VI and Fig. 3, we can obtain both the absolute value for  $P_1^\beta$  and the relative probability of ring closure.

In the transition from the 5- to the 7-ring the *a priori* probability falls by more than 2 powers of 10, and by increasing the length of the chain by a further 7 to 10 members the probability falls again by 3 to 4 powers of 10. The first step fall depends as already explained on the transition from the plane to the spatial forms. The velocity of the reaction shows even greater differences, which are attributable to small differences of activation energy.

The many-membered rings have in xylene at  $128^\circ$  a period of half-completion of three months, and therefore in this case only the order of magnitude of the temperature function can be ascertained. More minute differences between 12-, 14-, and 17-rings would be known from a study of the reactivity of the iodine derivatives, but an objection must be raised here to the value of very exact measurements which attempt to indicate very minute differences. From the temperature function of the reaction the mobility of the molecule can be determined. Now the mobility of the molecule itself and the spatial packing of the solvent are dependent on temperature, and these temperature functions can greatly distort the kinetic data. It would be much more rigorous to measure the temperature coefficient of the reaction velocity at constant volume and not at constant pressure.

It might be expected that in the preparation of the large rings in aqueous alcohol, very complicated circumstances would be encountered. For reasons which will be explained in the next section, only the order of magnitude of the values given in Figs. 3 and 4 for this solvent is correct.

<sup>21</sup> Moelwyn-Hughes, *loc. cit.*,<sup>21</sup> pp. 107 and 111.

One can see, however, that the *a priori* probability for the formation of a 17-ring in 30 per cent. isopropyl alcohol is not essentially different from that for a 7-ring. It is merely that the  $C_{16}$  chain is very insoluble in this solvent. (Solubility in 30 per cent. ethyl alcohol is only 0.002 mol./litre.) The energy differences between aqueous alcohol and the  $C_{16}$  chain are essentially larger than with  $C_5$  or  $C_6$ , so that the ring position will be favoured. Corresponding to the 7-ring in water, the preparation of the 17-ring in aqueous alcohol requires an anomalous energy of activation, which anomalous value is not met with in xylene solution. In the formation of the 15-, and 14-rings in the same solvent, smaller probabilities of formation are encountered. This can be connected just as well with the higher solubility and therefore greater mobility of the chain as with a steric hindrance of the reaction.

Whilst a transition from 30 to 10 per cent. alcohol in the preparation of the 6- and 7-rings results only in doubling the velocity of the reaction, the formation of the 12-ring in 10 per cent. aqueous alcohol at  $73^\circ$  is 4 to 5 times quicker than in 30 per cent. alcohol. This change corresponds roughly to the effect caused by a transition from 10 per cent. alcohol to water in the formation of the 7-ring at  $74^\circ$ . Correspondingly the solubility of  $C_{11}$  in 10 per cent. isopropyl alcohol is as small as the solubility of  $C_6$  in water (Table III.) Thus we may summarise what is known: the solubility goes parallel with the capillary chemical influence of the solvents on the arrangement of the molecule, and therefore also on the reaction velocity. This relation between the hydrocarbon chain and the solvent is characterised by  $\lambda$  values of the same order of magnitude. It will be remembered that these  $\lambda$  values determine the energy differences between the cylindrical and spherical shape of one molecule in a capillary inactive solvent. The following table of isocapillary forces between chain and solvent can be drawn up:

$CH_2$ -groups	5.	6.	11.	16.
$\lambda \times 10^{14}$ erg molecule.				
10	$\frac{Br(CH_2)_5NH_2}{\text{water}} \sim$	$\frac{Br(CH_2)_6NH_2}{10\% \text{ isopropyl alc.}} \sim$	$\frac{Br(CH_2)_{11}NH_2}{30\% \text{ isopropyl alc.}} \sim$	$\frac{Br(CH_2)_{16}NH_2}{90\% \text{ alc.}}$
40	--	$\frac{Br(CH_2)_6NH_2}{\text{water.}} \sim$	$\frac{Br(CH_2)_{11}NH_2}{10\% \text{ isopropyl alc.}} \sim$	$\frac{Br(CH_2)_{16}NH_2}{30\% \text{ isopropyl alc.}}$

### Methods and Results of Kinetic Analysis.

The synthesis of the large cyclic imines in homogeneous solution is affected by a number of secondary and side reactions. Beginning with the fact that every bimolecular reaction is dependent on concentration, whilst the ring closure reaction is entirely independent of concentration, it was possible by kinetic analysis to work out the conditions favourable for the synthesis. With a few grams of starting material it was possible to obtain quantitative relationships and by combining the figures so obtained with the results of a few preparative experiments, the causes and extent of the disturbances can be almost completely explained. The course of the analysis is as follows:—

The reactions of group (I) are kinetically identical and can only be separated by the investigation of the reaction products. If group (II) represents the main reaction, the concentration of the total amine groups, (primary, secondary and tertiary) remains approximately constant. One obtains reactions of the first order, the velocity of which, in contrast to (I) is still dependent on the concentration of bromamine ( $A_0$ ). It is best therefore to use a simple graphic method, to find out that concentration in which the reaction velocity is independent of the initial concentration ( $A_0$ ).

Fig. 5 represents an example of this type of the formation velocity of the 14-ring in aqueous alcohol. In this case the disturbance (II)

FIG. 5.

Solvent: 30 per cent. isopropyl alcohol.  $t = 73.4^\circ$ .

falls between  $A_0 = 0.0025 \text{ mol./litre}$  and  $A_0 = 0.005 \text{ mol./litre}$  within the limits of experimental error. By changing the hydroxyl ion concentration at this dilution the part played by the hydrolysis (III) can be determined very accurately. Now we still have to determine that part of the polymers which fall within the limits of experimental error of the

method. For the primary polymerisation we have

$$dA/dT = -k_1A - k_2A^2 \quad (1)$$

From the known accuracy of measurement and the observed disturbance  $k_2$  is calculated. Since the reaction is observed by the increase of bromo ion and not by the decrease of bromamine, only half of the disturbance which occurs in the expression (IIa) is measured. This is taken into consideration in the calculation of  $k_2$ . For the amount of imine ( $B$ ) and polymers ( $D$ ) formed, the following expressions hold:—

$$dB/dT = k_1A \quad (2)$$

$$dD/dT = k_2A^2 \quad (3)$$

and substituting  $k_1/k_2 = f_1$  we obtain from (1) and (2),

$$B = f \ln \frac{f + A_0}{f + A} \quad (4)$$

and from (1) and (3)

$$D = A_0 - A - f \ln \frac{f + A_0}{f + A}$$

For the secondary polymerisation (IIb) no such simple relations hold. Experience, however, shows that the disturbance can be satisfactorily calculated when the decrease of the imino group caused by polymerisation is neglected. This is probably due to the fact that another secondary reaction, namely

If one can therefore treat (IIb) as a disturbance, we have the following

$$dB/dT = k_1A - k_3AB \quad (7)$$

and substituting in (7)  $A = A_0 - B$ , we obtain a turning-point for the condition  $k_3A_0 > k_1$

$$B_{\infty} = \frac{k_3A_0 - k_1}{2k_3} \quad (8)$$

If  $k_1$  is known,  $k_3$  can be calculated from (8). The constant  $k_3$  so derived can be better obtained if some imine is added initially and the disturbance thus increased. It is, however, not possible to determine the proportion of polymers at a definite dilution from  $k_1$  and  $k_3$ . The following equation holds good for the polymers formed here, if we substitute  $k_1 : k_3 = g$ .

$$A - B = 2g \cdot \ln \frac{g - B}{g} + A_0 \quad (9)$$

The graphic solution, for experimental reasons, does not enter into the matter. On the other hand, an approximate solution is possible, for which I have to thank Dr. V. Weisskopf. If IIb occurs only as a disturbance, equation (9) can be developed according to powers of  $\epsilon$  and then becomes

$$B = 2\sqrt{2(A_0 - A)g + g^2} - [2g + (A_0 - A)] \quad (9)$$

The yields of monomers calculated with this formula is in good agreement with preparative experiments. The results of the kinetic analysis for one temperature are collected in Table VIII.

The far greater reactivity of the imines in comparison with those of the bromamines is surprising. Whereas the velocity of formation in the series 17-, 15-, 14-, 12-rings diminishes, the reactivity of the ring formed probably increases, this and the greater reactivity of the imines has a very unpleasant result in the preparations, as the ring formed subsequently polymerises with the unchanged starting material. Contrary to the primary polymerisation, the secondary polymerisation causes only a small increase in the constants of the first order. Thus calculations in agreement with the experimental data show that under conditions represented in Fig. 5, at  $A_0 = 0.005$ , 40 per cent. and at  $A_0 = 0.0025$  mol litre, 25 per cent. of secondary polymers are formed, whilst the deviation of the first order remains small. The limiting concentration given in Table VIII. is related to the secondary polymerisation. At this concentration one observes 25 to 35 per cent. polymers at complete conversion. An essential part of the secondary polymers is formed between the limits of 60 and 100 per cent. conversion, but the weight of the kinetic data is only considerable between the limits of 10 and 70 per cent. conversion.

The measured constants therefore represent infinite dilution in spite of the fact that polymers are formed. By empirical preparative researches, without kinetic analysis of the course of the reaction this particular reactivity of the imino group could not of course be demonstrated. Secondary bases usually have a larger dissociation constant than primary and tertiary. One might suspect a close relationship between the strength of the base and reaction velocity.

The hydrolysis constant  $k_H \approx 2 \times 10^{-2}$  corresponds well with that of the more reactive ethyl bromide ( $k_H = 7 \times 10^{-1}$ ) at this temperature.<sup>32</sup> The preparations were therefore carried out at a very low concentration of alkali. In accordance with the measured constants  $k_H$ , only 5 to 10 per cent. of the amino alcohol  $\text{HO} \cdot \text{CH}_2 \cdot (\text{CH}_2)_n \text{NH}_2$  was to be expected as a by-product. The preparative tests, however, in the case of the 17-ring gave 15 to 20 per cent., in the 15- and 14-rings, 20 to 40 per cent., and in the 12-ring 60 to 70 per cent. oxamine as "by-product." These deviations from the calculated yields are far beyond the limits of the experimental error of the method. A part of the oxamine must be formed not by hydrolysis but by a side reaction of the first order. This

<sup>32</sup> Hinshelwood and Grant, *J. Chem. Soc.*, 1933, 258.

type of reaction mechanism has recently been recognised for tertiary halogen alkyls, but on the other hand not for primary linked halogens.<sup>33</sup> For the halogenated amines the very unexpected course of the reaction becomes clear if the influence of the amino group on the ionisation process is taken into account:

The oxamine is formed as a result of the steric hindrance which is caused both by molecular structure and the hydration of the amino group. Since the oxamine is probably essentially less reactive than the ring formed, it polymerises to a lesser extent. Accordingly by the determination of yields the actual ratios are represented less favourably.

Nevertheless it cannot be doubted that the amino alcohol occurs as a result of reactions of the first order. The side reaction of course makes any conclusions from the temperature function more difficult to draw. It was, however, shown in the previous part how closely related the capillary activity of the solvent and the reaction velocity are for the 12-ring. If therefore instead of the ring, oxyamine is formed, the qualitative conclusions are not affected. The primary process of the thermal decomposition is, however, connected with the formation of a ring position.

### Ring Closure and Polymerisation.

The question now arises, when can polymerisation take place at all? For the limiting concentration  $c$ , in which ring formation is the main reaction, the following equation holds approximately

$$c \cong 0.1 \times \frac{k_1}{k_2} \quad (1)$$

If  $E_1 = E_2$ , then in (1)  $c = 0.1 \times \frac{Z_1}{Z_2}$ . If the values for  $Z$  are those demanded by the theory then

$$c \cong 0.1 \times \frac{10^{13}}{10^{11}} = 0.1 \times 10^2 = 10 \quad (2)$$

The meaning of (2) is that polymerisation can only take place in imaginary 10 molar concentration. In other words, the ring formation reaction is favoured even in systems of very high concentration. This results from the fact that for monomolecular reactions the velocity depends on atomic vibrations but bimolecular reactions on the much slower movements of molecules. Thus 5- and 6-membered-ring systems are formed in good yields in concentrated solution. On the other hand, the formation of 3- and 7-membered-rings in water takes place with an activation energy which is essentially greater than in bimolecular reactions. Accordingly the limiting concentration  $c$  becomes dependent on temperature. The

<sup>33</sup> Hughes and Ingold, *J. Chem. Soc.*, 1935, 244. Hughes, *ibid.*, 255.

3-ring has such a favourable  $Z$  value (Fig. 3) that at  $37^\circ$  it is formed even in 0.2 molar solution. The  $Z$  value of the 7-ring is also favourable, but is already 50 times smaller and this suffices to reduce the limiting concentration to 0.005 mol./litre, somewhat higher concentrations can be used for the synthesis of the 7-ring in aqueous alcohol. The velocity of formation of the 17-ring in this solvent is only 20 times smaller (Table 8) and the limiting concentration is therefore of the same order of magnitude. Thus the speeds of reaction and limiting concentrations go through a minimum between the 7- and the 17-ring.

TABLE IX. —FORMATION OF THE 14-RING AT  $73.35^\circ \text{C}$ 

Solvent.	$k_1$ .	$k_2$ .	$c$ for $k_1$ .	$c$ for $k_2$ .
30 per cent. Isopropyl .	0.0007	0.015	0.005	0.0025
Toluene . . . . .	0.00000009	0.004	0.00002	?

The circumstances in capillary active solvents are quite different. Whilst at  $73^\circ$  the speed of formation of the 7-ring in toluene is 80 times smaller than in 30 per cent. alcohol, it falls with the 14-ring to 800 times less. Since the bimolecular reactions in both solvents proceed with similar velocities (although with different temperature coefficients), for the synthesis of the 14-ring in toluene extreme dilution must be employed. Independently of the facts mentioned above, Table IX. shows clearly that *there is a specific relationship between solvent and reaction velocity*. The synthesis of the 14-ring in toluene proceeds at  $73^\circ$  to the extent of 99 per cent. in ten years, and at  $128^\circ$  in one year. Now we have at our disposal no method of separating the starting material from the final product, therefore it is impossible to prove that the ring is formed under the conditions given in Table IX. But for our conclusions the only important fact is the very small velocity of the reaction (independent of concentration), which causes the measurable changes in the order of magnitude of the limiting concentration. If instead of the ring, an isomeric compound is formed or if the ring is subsequently resinified, it does not in the slightest alter the fact that the velocity of the monomeric reaction is influenced 200 times more by the solvent than is the polymerisation reaction. On account of the exponential form of the temperature function the differences in velocity between iodine and bromine derivatives at high temperatures are small, being in the ratio of about 8:1. Consequently, the ring closures in xylene with the iodo amines proceed also too slowly to afford any proof of preparation.

In addition to polymerisation and the monomolecular reaction even reaction with the solvent can disturb the ring formation. In absolute alcohol, for example, the speed of etherification is of a similar order of magnitude to the speed of ring closure. Nitrobenzene was an exceptionally suitable solvent, except that it contained an active impurity (nitrophenol?). By working in very dilute solution an impurity in the solvent amounting to one millimole per litre is sufficient to disturb the speed of the ring closure. On the other hand the formation of the 6-ring in the same solvent proceeds so quickly and at so low a temperature that the impurities are absolutely inactive. On the same grounds the subsequent resinification of the large imines plays an appreciable rôle. If Ziegler's

method of dilution and reactions of long duration are anomalous in the practice of organic chemistry, the use of these methods resulted in entirely unexpected sources of error.

### Strained Ring Systems.

Whilst the normal and higher membered rings which have been already referred to are stable to the halogen acids in dilute solution, the 3- and 4-membered rings imines are converted to the halogenated amines. The corresponding ring closure reactions, however, proceed to completion in alkaline solution, where the concentration of hydrogen ion remains small. In place of the equilibrium therefore, we have in alkaline solution a stationary condition. If on the other hand we have bromoethylamine in benzene, the following equilibrium is set up:

But instead of being as simple as this, very complicated processes take place. One sees from previous measurements that the equilibrium lies chiefly on the side of the bromoethylamine, which, however, is slowly removed from the equilibrium system by a slow primary polymerisation. This is very probably what occurs.

The breakdown of the ring systems is very strongly exothermic

In aqueous solution one finds in reaction (1) 5 K-Cal., and in (2) 10 K-Cal. less activation energy than is demanded by the ring closure reaction. Styroilimine is rearranged instantaneously in toluene solution even at  $-50^\circ$  by HCl gas, so that this reaction requires only a very small energy of activation.

The formation of strained rings is thus, in contradiction to all other ring closures above, dependent on the  $p_H$  of the reaction mixture, so that it is not remarkable that the influence of alcohol on the reaction velocity in aqueous alcohol is large. This is in opposition to the Langmuir theory. In the 3- and 4-membered carbon chains there can be no difference in energy between the chain position and the ring position exceeding  $kT$ . But it depends here more on the spatial packing of the molecular compound which results. This compound, once formed in a capillary inactive solvent has probably a greater stability than in organic solvents.

For the preparation of strained rings an additional energy of activation is necessary (Fig. 4). The differences are, however, less than would be expected on the ground of the energy content (heat of combustion of cyclo-butane and cyclo-propane), and the small stability of the ring systems. The reaction is made less difficult by the halogen group in the  $\beta$  or  $\gamma$  position to the amino group.

As already explained, the large *a priori* probability of the formation of the 3-ring depends on the resonant action of the three atomic groups,

and also perhaps on the favourable spatial packing in water. It is astonishing that the *a priori* probability is at a minimum with the 4-ring, but this is probably due to the smaller resonance, higher mobility of the chain and deviation of the valencies. Perhaps, however, something else is decisive. The researches on the Raman spectra<sup>34</sup> of various butane derivatives shows that of the two possible forms the "zig-zag" form occurs much oftener than the "Wanne" form. Since it is this latter which is converted into the ring, it is the limitation of the free rotation of the chain determines the velocity of the reaction.

### Comparisons with Other Ring Closure Reactions.

Bennett<sup>35</sup> and co-workers investigated a similar ionogenic reaction  $R \cdot S \cdot (CH_2)_n Cl \rightarrow (R \cdot S \cdot (CH_2)_n)^+ Cl^-$ , and Table X. shows how closely related both ring closures are.

TABLE X.

Reaction.	Solvent.	Ring	E.	H
$Cl-(CH_2)_n-S-C_6H_5$ $\rightarrow [C_6H_5-S-(CH_2)_n]^+ Cl^-$	50 per cent. Acetone	5 6	23.4 23.9	11.0 10.0
$Cl-(CH_2)_n-NH_2$ $\rightarrow (CH_2)_n-NH \cdot HCl$	Water	5 6	19.4 20.0	12.2 11.4
	30 per cent. Isopropyl alcohol	6	19.8	10.1

The following reaction was further developed by Ziegler<sup>36</sup> to the preparation of an imine derivative:

Preparative experiments have already shown that the reaction requires a large energy of activation. The synthesis of the 7-ring was accomplished as with the bromamines, at a dilution of the order of magnitude 0.01 mol./litre.

Ziegler's synthesis of the ketoimides is of an essentially different character; only the ring closure phase is given here:

A is alkali metal.

<sup>34</sup> Kohlrausch, *loc. cit.*

<sup>35</sup> Bennett, Heathcote, Mosses, *J.C.S.*, 1929, 2507.

<sup>36</sup> Ziegler and Orth, *Ber.* 1933, 66, 1867.

The corresponding bimolecular reaction has between 25° and 36° a perceptible temperature coefficient. The energy of activation therefore must be at least 10 K-Cal. For the preparation of the 17-ring in boiling ether, a half-change period of the order of seconds or minutes was necessary, and the corresponding half-change period for the preparation of the 17-ring from the bromamine under the same conditions would be 10<sup>5</sup> hours. This extreme difference depends not only on a greater activation energy for imine preparation, but also on the more favourable steric factors in the ketimide reaction. Whilst the ionogenic reaction in organic solvents proceeds slowly, this is obviously not the case in the ketimide synthesis. One can therefore expect that the bimolecular ketimide reaction proceeds with the velocity given by the collision theory. The ketimide is subsequently saponified to the ketone. Since the reaction products obtained here are unreactive, it is only by estimation of yields that conclusions may be drawn.<sup>37</sup>

The large field of reversible ring closure reactions opened up by the method of depolymerisation developed by Carothers.<sup>38</sup> According to Carothers<sup>39</sup> the classical ketone synthesis of Ruzicka from the thorium salts of the dicarboxylic acids is due in part to a depolymerisation process. According to Langmuir long-chain molecules assume in the vapour phase the spherical or ring form, and this circumstance would contribute essentially to the success of such reactions. Ziegler<sup>40</sup> had neglected the application of the dilution principle to reversible reactions. It is easy to understand how in the dilute systems reversible reactions would be accompanied by side and secondary reactions. These circumstances accidentally prove to be very important in the preparation of many-membered lactones.<sup>41</sup> The synthesis of these important perfumes was accomplished by Ziegler's<sup>41</sup> method. In dilute benzene solution, the equilibrium is continually disturbed

by distilling off the water formed. Kinetically, the system is undefined since the process which defines the reaction velocity cannot be isolated, and conclusions drawn from yields or combinations of yields and kinetic measurements are also difficult to explain. Polymerisation by "Re-esterification" may occur thus:

Generally, one would not turn to the discussion of molecular statistics for catalytic reactions. In the first place a three-body collision with the catalyst is necessary and the shape of the molecule is then undetermined. Esterification in moist organic solvents appears to be bound up with the fulfilment of an acidity condition which corresponds to  $p_H$  in aqueous solutions. We have at our disposal, then, only two types of reaction which will allow us to attempt to solve the polymerisation problem statistically: ionogenic reactions and the ketimide synthesis.

<sup>41</sup> M. Stoll and A. Rouvé, *Helv.*, 1934, **17**, 1283.

During the last ten years there has been no lack of attempts to explain thermodynamically the "catalytic" influence of solvents on reaction velocity. Above all, the Van't Hoff-Dimroth theory should be remembered. According to these workers there should be a relationship between solubility, chemical equilibrium and reaction velocity. For ionogenic reactions, therefore, this explanation is insufficient as the dielectric constant of the medium is important. In inter- and intramolecular reactions, however, it appears that, in addition to the dielectric

constant, the spatial packing of the complex  $R \cdot \begin{array}{|c|} \hline H_2N \quad Br \\ \hline \text{solvent} \\ \hline \end{array} \cdot CH_2 \cdot R$  de-

termines the velocity. The ideas are similar to the old Van't Hoff theory, except that instead of the macroscopic equilibrium, the microscopic intermediary is considered. As long as we do not succeed in realising every typical chemical force which solubility can exert there is little hope of success in finding a quantitative relation between reaction velocity and solubility.

In the special case of the ring closure reactions we have moreover the complicated reaction mechanisms, simple relationships between capillary activity of solvent, shape of molecules, and speed of reaction.

I should like to take this opportunity of thanking Professor H. Freundlich for his warm interest in this investigation and Professor L. Ruzicka for the hospitality of his laboratory. My special thanks are due to the co-workers of Professor Ruzicka for their frequent and friendly advice which has so facilitated the execution of this work. I thank Mr. J. D. Rose for translating the manuscript.

### GENERAL DISCUSSION.

**Professor R. Signer** (Bern) said. In order to determine the form of fibre molecules in solution there are nowadays viscosity measurements, the determination of double refraction of flow and other methods available. The kinetic measurements of Salomon provide a criterion of the most probable form of the molecule of terminally halogenated amines. These molecules have two terminal groups with strong dipole moments, which will influence the distribution of the molecular form in solution. With regard to the first-named methods, one is led to ask whether from his kinetic measurements Salomon is in a position to say something as to the most probable form of the normal hydrocarbon molecule in organic solvents such as benzene, carbon, tetrachloride, etc.

**Mr. W. F. K. Wynne Jones** (Reading) said. According to the results presented in Table I., ring-closure reactions involving halogen alkylamines proceed at a normal rate in water, but at a rate which is about  $10^4$  times too slow in non-aqueous solvents. The theory of the activated complex predicts a normal rate wherever the activated state closely resembles the original state of the reacting molecules. For reactions of the type considered here, the theory therefore indicates that in water the reacting molecules are strongly polar and curled up in a ring form, since it is most probable that in the activated state ring formation is practically complete and the hydrogen and halide ions are in the act of leaving the complex.

In non-aqueous solvents the difference between the activated and normal states is evidently great, and this suggests that the normal state is much less polar than in water; such a change in polarity is well known in the amino-acids. Of course, any interpretation of the data in terms of a specific mechanism is dependent not only upon the reliability of the data, but also upon the assumption that the observed reaction behaves in a simple manner kinetically, but with these reservations the theory of the activated complex enables us to draw conclusions from rate measurements.

**Dr. E. A. Moelwyn-Hughes** (*Cambridge*) said: As Dr. Salomon has observed, there is a striking parallelism between the kinetics of the formation of piperidine hydrochloride and those of the formation of tetraethyl ammonium chloride in their response to different solvents (Table VI.). It therefore seems that the adoption, at least provisionally, of the Wigner and Polanyi figure of  $10^{13}$  seconds<sup>-1</sup>, or of the exact Raman frequency of the breaking bond, enables us to classify unimolecular behaviour in roughly the same way as the adoption of the gas-kinetic figure of  $2.8 \times 10^{11}$  seconds<sup>-1</sup> (gram-moles per litre)<sup>-1</sup> enables us to classify bimolecular behaviour. The parallelism revealed in the table is, however, quite independent of the value of  $Z_{\text{uni}}$ , or of  $Z_{\text{bi}}$ , which we accept as a kind of standard, and suggests that, of the various factors which are included comprehensively in the term  $P$ , at least one important factor is common to both sets of experiments. Another factor of possible significance for these reactions has been recently discussed.<sup>42</sup>

With regard to Professor Ziegler's work on the union of two triphenylmethyl radicals, I do not think it is fair, until we have data for the reaction in the gaseous phase, to conclude that this reaction is slowed down by the solvent.

I have been fascinated by Dr. Salomon's ingenious method of calculating the statistical distribution of the various geometric forms of chain-like compounds in solution with the surface energies involved, and by his suggestion that such a distribution may contribute yet another factor to the complicated term  $P$ . As far as the reactions discussed here are concerned, it is difficult to gauge the amount of truth contained in the suggestion; but the method of attack is a novel and interesting one, and should yield further results of great value. If, in the present case, the mechanism is a relevant one, it appears to me that the form of the velocity constant concentration curve should throw some light on the problem. Provided

FIG. 1.

one geometric configuration were chemically more reactive than another, the form of the curve ought to be very sensitive to the magnitude of interfacial energy,  $\lambda$ . I should therefore like to ask Dr. Salomon what is the experimental range in which it is true to say

that "ring closure is independent of concentration?"

**Professor H. Mark** (*Wien*) said: The measurements of Dr. Salomon seem to show that in the case also of ring formation in solution, an effect takes place analogous with that in the case of polymerisation and association

<sup>42</sup> Moelwyn-Hughes and Sherman, *Trans. Chem. Soc.*, in press, 1935.

of large molecules. The steric factors are not at all of the size which one would expect and may be compensated by another, as yet unknown, effect. One could think that, in some analogy to Volmer's ideas on crystal growth, and to the discussion which took place after my paper, the ends of a long chain do not diffuse in space at random until they approach one another, as shown in Fig. 1a, but that they are brought in contact by the internal van der Waals' forces, which bend the long molecules (Fig. 1b). The latter form of the molecule would have some analogy with the fact that large rings are built up of parallel chains, as shown in Fig. 1c.

**Dr. G. Salomon (Zurich)**, in reply, said: I agree perfectly with Mr. Wynne-Jones. The change of the rate of reaction in various solvents must be very closely connected with the properties and the life-time of the preformed molecular compound. For the first time we observe a reaction with the "normal" rate in water and a "slow" rate in organic solvents. According to Eyring we may assume that the mechanism of reaction is connected with a restriction condition, when the rate of reaction should be slow. This effect may be inhibited by a longer lifetime of the unactivated complex. It is very probable that, having regard to the strong dipole forces in water, the intramolecular compound formed is stable and the regeneration of the open chain requires a small activation energy. Another argument for this opinion results further from this investigation. In addition to ring formation a new kind of monomolecular hydrolysis appears as a side reaction. This can only be understood if the hydrated sheaths are very strongly bound to the complex. Nevertheless the change of electrostatic forces in this "ionogenic" reaction cannot be the sole reason of the slow rate in organic solvents. The recombination of triphenyl methyl radicals to hexaphenyl ethane belongs also to this type. I outlined in this paper that there may be a connection between the spatial packing of the complex and the life period. Polanyi and Evans<sup>44</sup> have recently drawn very similar conclusions, using the transition state method. It is difficult, however, to understand that two so different reactions as radical association and "ionogenic" reaction are restricted for the same reason. It may be possible that the same retarding effect follows from two very different causes. I believe that the kinetic test of a normal bimolecular amino condensation, for example,

will show that these "slow" reactions also become "normal" in water as solvent.

With Dr. Moelwyn-Hughes I believe it is right to be on the look out not only for "slow" but also for too fast reactions. But the hydrolysis he mentions in the discussion of Freudenberg's paper (page 75) is a much more complicated case than the one we are dealing with. As there are a series of different reactions of this type the temperature independent factor of which agrees well with Polanyi and Wigner's theory, there is no reason to neglect this idea as starting-point. It may nevertheless happen that by the indication of certain inner degrees of freedom the order of the Z-value increases and there may also be a small difference in the Z-value of the chloro-, bromo- and iodo-amines of the same chain according to the very different atomic weight of the halogen atoms.

Moelwyn-Hughes questions whether the geometrical equilibrium

Ring position  $\rightleftharpoons$  chain position

is not influenced by the concentration of the starting material. This certainly is right in concentrated solutions but not in dilution of 0.2-0.00002 mol./l. which are used for the kinetic experiments. Since large amounts

<sup>44</sup> *Trans. Faraday Soc.*, 1935, **31**, 875.

of solute change the character of the solvent, the interpretation of experiments in high concentrations is ambiguous.

Professor Katz' gave some interesting results though they are not directly connected with our problem. Even the knowledge of the shape of molecules in a pure liquid does not permit us to draw conclusions as to the shape of the same molecule dissolved in another liquid.

The problems discussed by Professor Signer are connected with the question: which is the most probable form of a chain molecule. The kinetic results give data only as to the relative and absolute probability of one shape of the molecule, namely the closed form. Thus, it is possible to say that even the five-membered chain is about 10-30 times more seldom formed closed in water than would be expected on purely statistical grounds. We are sure, moreover, that a 17-membered chain in organic solvents is about  $10^6$  times more seldom closed than is the 5-membered chain. If there is, however, a certain internal movement it seems to me, according to Kuhn's and Mark's calculations, impossible that the chain is really straight.

## THE KINETICS OF POLYMERISATION REACTIONS.

By C. E. H. BAWN.

*Received 4th September, 1935.*

It has long been recognised that the formation of a polymer of high molecular weight is a composite process, determined by a set of consecutive reactions. Some recent studies indicate that this process occurs via the successive addition of simple molecules to the growing complex. In these cases the total reaction process probably comprises a set of simple bimolecular association reactions between complex molecules. It is with this type of process that this paper is concerned.

The velocity constant of a bimolecular association reaction may be represented in the form

$$k = pZc \frac{E}{RT} \quad (1)$$

where  $Z$  is the total number of collisions between reacting molecules and  $p$  is a factor which takes into account the fact that not all collisions with the required energy lead to reaction. This factor is of especial interest since it broadly divides bimolecular reactions into two classes, (1) in which the factor  $p$  approaches the value of unity, and (2) in which  $p$  has a small value of the order of  $10^{-4}$  to  $10^{-8}$ . It has been pointed out by Hinshelwood and Grant,<sup>1</sup> that reactions in which one of the reacting molecules is an ion belong to the first class. The same is also true for bimolecular reactions of atoms. In the second group are included certain bimolecular reactions between large molecules ("slow reactions"), for example, processes in which tertiary nitrogen molecules form quaternary compounds with organic halides,<sup>2</sup> the recombination of free radicals<sup>3</sup> and polymerisation,<sup>4</sup> and hydrogenation reactions.<sup>5</sup> Generally it may be stated that association reactions involving molecules having a large number of degrees of freedom have small steric factors.

<sup>1</sup> Grant and Hinshelwood, *J. Chem. Soc.*, 1933, 258.

<sup>2</sup> Moelwyn-Hughes, *Kinetics of Reactions in Solution*, Oxford 1933.

<sup>3</sup> Zeigler, *Ann.*, 1929, 473, 163; 1933, 504, 124, 145.

<sup>4</sup> Pease, *J. Am. Chem. Soc.*, 1930, 52, 1138; 53, 613.

<sup>5</sup> *Ibid.*, 1932, 54, 1876.

It is obvious therefore that this factor will play an important part in any kinetic considerations of a composite polymerisation process. It has been shown in a previous paper,<sup>6</sup> that the application of the transition state method,<sup>7</sup> for the calculation of reaction velocities, to association reactions leads to a simple interpretation of the steric factor. It is only necessary, therefore, to give a short account of these calculations. According to the method of Eyring and Evans and Polanyi<sup>7</sup> the reaction velocity may be represented by

$$\text{reaction velocity} = \frac{1}{2} P v$$

where  $P$  is the probability of the transition state and  $v$  is the average velocity of the representative point at the top of the barrier, along the reaction co-ordinate  $l$ . This may be shown to be equal to  $\frac{1}{2} K \cdot v$  where  $K$  is the equilibrium constant between the initial and the transition state. Now both  $K$  and  $v$  may be calculated by the method of statistical mechanics together with a knowledge of the potential energy surface which represents the course of the reaction.

Thus in the general case of a reaction

where  $A$  and  $B$  are complex molecules  $K$  may be calculated from the partition functions of the molecules

$$K = \frac{f_{A \cdots B}}{f_A f_B} e^{-E_0/kT},$$

where  $E$  is the difference in energy between the initial and the transition state. The average velocity associated with the passage of the system across the transition state is  $\frac{kT}{(2\pi m^* kT)^{1/2}}$  where  $m^*$  is the reduced mass of the transition complex, so that the reaction velocity constant  $k_1$  is equal to

$$k_1 = \frac{f_{A \cdots B}}{f_A f_B} \cdot \frac{kT}{2\pi m^* kT} e^{-E_0/kT} \quad (2)$$

By comparison with equation (1) it is seen that the first term in the above expression now replaces \* the factor  $pZ$ . If this expression could be separated in the correct way it would be possible to obtain the absolute values of  $p$  and  $Z$ . However, this requires some assumptions as to the detailed mechanism of the reaction, and for the present the approximate magnitude of  $p$  may be obtained by comparison of the calculated factor with  $Z$  as obtained by the ordinary kinetic theory method. Before we give the results of these calculations, further considerations will show clearly the origin of the steric factor. If the expression analogous to (2) is written down for a similar reaction between atoms, a comparison of the probability factor for the transition state in these two cases shows immediately that for complex molecules the probability is very much decreased. This decreased probability appears in the kinetic expression for the reaction of the complex molecules as a steric factor.

\* *Trans. Faraday Soc.*, 1935, **31**, 1536.

<sup>7</sup> Eyring, *J. Chem. Physics*, 1935, **3**, 107. Evans and Polanyi, *Trans. Faraday Soc.*, 1935, **31**, 875.

\* This is not exact since a small term will have to be included to allow for the fact that  $E_0$  in equation (2) and  $E$  in (1) are defined differently (see ref. 7).

It may now be seen, by tracing the change in the degrees of freedom which occur, how the reduced probability in the reactions of complex molecules arises. In the association reaction of atoms two degrees of translation in the initial state pass over to two degrees of rotation in the transition state. This roughly corresponds to the collision diameter in the kinetic theory picture. In the case of the reaction between complex molecules, *e.g.*, the association of two radicals, two degrees of freedom of translation and three of rotation go to five degrees of vibration in the transition state. The steric factor can now be correlated with the change from rotational to vibrational degrees of freedom.

### Calculation of the Steric Factor for some Association Reactions.

The equilibrium constant of an association reaction may be written in the form

$$K = \frac{k_{\text{uni}}}{k_{\text{bi}}} \quad (3)$$

where  $k_{\text{uni}}$  and  $k_{\text{bi}}$  are the velocity constants for the forward and reverse reactions respectively. If the unimolecular part of the reaction involves no steric factor, then the full magnitude of the steric factor of the bimolecular reaction will make its appearance in the equilibrium constant. The former assumption will be generally true since the configuration of the transition state of the unimolecular reaction will be very similar to that of the initial state<sup>8</sup>—it will probably differ only in one co-ordinate along which decomposition is occurring.

The following table gives the steric factors of some simple reactions calculated by use of (3). The equilibrium constant was determined from the partition functions of the molecules.<sup>9</sup> The value of  $p$  was obtained by comparing  $k_{\text{bi}}$  calculated from (3) (it being assumed that

TABLE I.

Reaction.	Temperature °C.	K (atm.)	$p$ .

$\text{CH}_3 + \text{CH}_3 \rightleftharpoons \text{C}_2\text{H}_6$	1500	$7.43 \times 10^{-8}$	$10^{-4} - 10^{-5}$
$\text{CH}_3 + \text{COCH}_3 \rightleftharpoons \text{CH}_3\text{COCH}_3$	1500	$2.75 \times 10^{-11}$	$8 \times 10^{-6}$
$\text{CH}_3 + \text{C}_2\text{H}_5 \rightleftharpoons \text{C}_2\text{H}_6$	800	$9.0 \times 10^{-9}$	$10^{-4} - 10^{-5}$
Log $K_p$ (atm.).			
$\text{N}_2\text{O}_4 \rightleftharpoons 2\text{NO}_2$	—	$-\frac{13600}{2.3 RT} + 9.0$	$2 \times 10^{-6}$
$\text{C}_2\text{H}_6 \rightleftharpoons \text{C}_2\text{H}_4 + \text{H}_2$ <sup>10</sup>	—	$-\frac{31244}{2.3 RT} + 6.31$	$1 \times 10^{-2}$
$\text{C}_2\text{H}_4 + \text{H}_2\text{O} \rightleftharpoons \text{C}_2\text{H}_5\text{OH}$ <sup>11</sup>	—	$\frac{9600}{2.3 RT} - 6.20$	$1.4 \times 10^{-4}$

<sup>8</sup> This assumption was employed by Polanyi and Wigner (*Z. physik. Chem., Haber Band*, 1928, 439) in their derivation of the well-known relationship  $k_{\text{uni}} = \nu e^{-E/RT}$ .

<sup>9</sup> Cf. ref. 6 for details of these calculations.

<sup>10</sup> Pease, *J. Amer. Chem. Soc.*, 1932, **54**, 1876.

<sup>11</sup> Stanley, Yould and Dymock, *J. Soc. Chem. Ind.*, T., 1934, **53**, 206.

$k_{\text{uni}} = 10^{13} e^{-E/RT}$  where no experimental determination was available) with the corresponding value of the collision theory. The last three results in Table I. were calculated from the experimentally determined temperature dependence of the equilibrium constant. It can be seen from these results that association reactions between molecules involving a large number of degrees of freedom have small steric factors, whereas with reactions involving atoms the steric factor tends to unity. These conclusions are strongly supported by experimental measurements of the rates of such reactions. (Table II.)

TABLE II.

Reaction.	$B.$ $(\log k = B$ $- E/2.3 RT)$	$E.$	$p$ (600° C.).
$H_2 + C_2H_4 \rightarrow C_2H_6$ <sup>10</sup>	—	35,700	$4.5 \times 10^{-3}$
$2C_2H_4 \rightarrow C_4H_8$ <sup>11</sup>	10.85	38,400 (40,300)	$4 \times 10^{-3}$ $(3 \times 10^{-3})$
$2CH_2 = CH - CH_2 \rightarrow C_6H_{12}$ <sup>12</sup>	10.2	38,000	$1 \times 10^{-3}$
$2CH_2 = CH - CH_2 \cdot CH_3 \rightarrow C_6H_{14}$ <sup>12</sup>	10.0	38,000	$5 \times 10^{-4}$
Amylene <sup>12</sup>	9.8	38,000	$4 \times 10^{-4}$
$2 \begin{smallmatrix} CH_3 \\   \\ CH_2 \end{smallmatrix} \cdot C = CH_2 \rightarrow C_6H_{16}$ <sup>12</sup>	12.3	43,000	$1 \times 10^{-1}$
$2CH_2 = CH - CH = CH_2 \rightarrow C_6H_{12}$ <sup>13</sup>	—	25,300	$1 \times 10^{-4}$
$2CH_3 - C \begin{smallmatrix} \diagup CH_3 \\ \diagdown CH - CH_3 \end{smallmatrix} \rightarrow C_{10}H_{18}$ <sup>14</sup>	—	28,900	$1.0 \times 10^{-2}$

Before extending the application of these ideas to complex polymerisations the theoretical conclusions may be summarised as follows:

(1) On account of the decreased probability of the transition state bimolecular association reactions between complex molecules will have a much smaller steric factor than the corresponding reaction in which one or both of the reaction partners is an atom. In the latter case the value of the steric factor tends to unity.

(2) The steric factor will for a series of similar reactions decrease as the number of degrees of freedom of the associating molecules increase.

(3) In comparing dissimilar reactions account must also be taken of the configuration of the transition state. The transition state may be considered as a potential hollow of  $3N - 7$  dimensions and the volume of phase space corresponding to it will be determined by the restriction of position placed upon the molecules in the transition state. Since this phase volume is proportional to the probability of the state any increased restriction of position will decrease the probability and thus the steric factor. Thus the third conclusion may be stated—the greater the restriction of position of the reacting molecules in the transition state the smaller the steric factor.

### Polymerisation as a Chain Reaction.

Polymerisation reactions are known to show many of the characteristics of chain reactions.<sup>15</sup> The evolution of the polymeric molecule may be imagined to proceed by the successive addition of single or more complex molecules to the growing complex. As an example the following type of chain may be considered. The polymerising molecule A may be activated either thermally or photochemically and this activated molecule then combines with another molecule of A to give a dimer. It is further assumed that the dimer is produced in an activated condition, the activation being produced by the energy of reaction. This process continues until either the intermediate active polymer becomes deactivated or that it is incapable of adding more molecules for chemical reasons. The total process may be represented by the following scheme,\*

it being assumed that the dimers, trimers, etc., do not react among themselves. Now from our previous considerations if A is a complex molecule each succeeding step in the reaction chain requires a smaller steric factor. That is, as the chain length increases, reaction becomes more difficult and will finally become immeasurably small. The length of the chain and hence the size of the polymeric molecule will therefore reach an apparently limiting value and this will be determined primarily by the magnitude of the steric factor.†

In drawing these conclusions it has been assumed that all unit reactions in the chain require no activation energy. If such reactions needed activation it might be suggested that this energy decreased at each stage in the reaction and that this annuls the effect of the decreasing steric factor. The fact that the reaction chain extends to any considerable length excluded this and, furthermore, experimental evidence indicates that the association of radicals which are probably intermediates<sup>16</sup> in the chain needs no activation energy.

<sup>15</sup> Semenoff, *Chemical Kinetics and Chain Reactions*, Oxford 1935, p. 444.

\* A well known example of this type of process is the polymerisation styrene or vinyl acetate. Both of these reactions are known to proceed by a chain mechanism. The initial process is most probably the opening of a double bond,

the active molecule then adding another molecule of the monomer, the energy change being sufficient to give an excited dimer which may carry on the chain in the following way.

† There are several possible variations of the foregoing reaction scheme, for instance: the initial reaction  $A + A \rightarrow A_2$  may give a dimer which does not participate in a reaction chain. The possible subsequent reaction of the dimer (say with another molecule of A) would need an activation energy and similarly for the reaction of higher polymers. In such cases the resulting polymeric mixture when all of A has disappeared would consist almost entirely of lower polymers, the concentration of the dimer being much greater than that of the trimer, the concentration of the trimer greater than that of the tetramer and so on.

<sup>16</sup> Rice and Sickman (*J. Amer. Chem. Soc.*, 1935, **57**, 1384) have recently found that methyl radicals initiate the polymerisation of ethylene.

Further information can be obtained by a consideration of the reverse process, namely, the breakdown of a long chain, or large polymeric molecule. A molecule built up of  $n$  unit molecules of A may break in any one of the  $n - 1$  bonds, the two limiting reactions being given by

Since the association reaction is more difficult for the larger molecule, then, if the unimolecular dissociation is assumed to require the same activation energy independent of the bond which breaks, the equilibrium constant of (1) will be shifted much further to the right than that of (2). Thus, if the equilibrium is established the products of the breakdown in the middle of the molecule will be more abundant than those corresponding to dissociation at the end of the chain. This is also in general agreement with many observations on the cracking of hydrocarbons.<sup>6</sup> It is also well known that the stability of the hydrocarbon molecule decreases with increase in chain length, as is also true for large polymeric molecules. In other words  $k_{\text{uni}}$  actually increases with increasing chain length and, since  $k_{\text{bi}}$  decreases under the same conditions, it may be concluded that for any similar series of long chain molecules the equilibrium corresponding to the breaking of any given bond will be displaced more to the right the longer the length of the molecule.

### Summary.

The steric factor of bimolecular association reactions has been discussed. The application of the transition state method for the calculation of reaction velocities leads to a simple interpretation of this factor in terms of the probability of the transition state. The steric factor of some polymerisation reactions has been evaluated. On the assumption of a chain mechanism of polymerisation it is shown that the chain length and thus, the size of the polymeric molecule, is determined by the magnitude of the steric factor.

In conclusion, the author wishes to thank Professor M. Polanyi for many helpful discussions.

*The University,  
Manchester.*

### GENERAL DISCUSSION.

Dr. H. Dostal (Wien) said. If the reaction constants of chain growth,

$k_n$  depend on the degree of polymerisation (or chain length, which is the same)  $n$ , our method of calculating the amount of polymer at any time, and the distribution of the molecular weights in the polymer, cannot be applied immediately. With regard to the steric factor, the function  $k_n$  of  $n$  can, for instance, be given by

$$k_n = A\alpha^n.$$

the steric factor. Whether we should, with E. Hückel, take into account the phase volume, or whether we must choose another possibility, cannot as yet be said with certainty. In any case, however, it seems that a further systematic study of the dissociation reactions of big molecules (independent of the solvent) seems to be mostly in demand.

**Dr. E. A. Moelwyn-Hughes** (*Cambridge*) said: The theory of Polanyi and Eyring is essentially an equilibrium theory. How far does Dr. Bawn consider it logical to apply this theory to a system involving a chain reaction, which only under highly specified conditions can be treated as a system at equilibrium? I should also much appreciate any comments which Dr. Bawn might feel disposed to make on some of the postulates underlying the theory of Eyring and Polanyi, particularly (1) the mutual independence of the various intermolecular motions which is implied in the evaluation of the corresponding partition functions, and (2) the force-free field postulated for the translatory motion in the co-ordinate of decomposition.

**Mr. M. W. Perrin** (*Northwich*) said: In connection with the "transition state" method of treating reaction kinetics, I should like to mention some preliminary results which have recently been obtained for the influence of hydrostatic pressure on the rate of polymerisation of linseed oil. Estimating this rate by the time taken to produce an oil of any given viscosity, it has been found that a pressure of 3000 kg./cm.<sup>2</sup> accelerates the reaction about ten times. At a temperature of 280° C., where the reaction is so slow at atmospheric pressure that a time of some days is necessary to reach a high viscosity, it has been found that the oil is polymerised to a hard gel in about one hour under a pressure of 12,000 kg./cm.<sup>2</sup>

Until more experimental data is available, it is not possible to make an exact numerical comparison with the theory put forward by Evans and Polanyi,<sup>18</sup> but it appears that the pressure effect is of the order of magnitude predicted for a polymerisation reaction of the "slow" type with a steric factor much smaller than unity. It is hoped that further work, now in progress, will enable more definite conclusions to be drawn as to the mechanism of the pressure effect.

**Mr. W. F. K. Wynne-Jones** (*Reading*) said: The theory of the activated complex or transition state as developed by Eyring,<sup>19</sup> and by Evans and Polanyi<sup>20</sup> leads, as shown by Bawn, to a decreased probability for the formation of complex molecules. It is, however, important to note that for reactions occurring in solution the association of solvent molecules with the activated complex or the reacting molecules may have a preponderating influence, as has already been shown for certain reactions.<sup>1</sup> The criticism raised by Moelwyn-Hughes refers to the exact calculation of the partition function for the activated complex, and does not reflect on the principle of the method, nor does it affect the general conclusions that may be drawn as to reaction mechanism. It has already been shown in several studies made by Eyring and his co-workers that abnormal rates of reaction in the gaseous state can be exactly treated by this method.

**Professor Paul N. Kogerman** (*Tartu*) said: In spite of the great importance of physico-chemical methods and mathematical analysis for the study of the phenomenon of polymerisation, especially for elucidation of the kinetics of the reaction, one should nevertheless not exclusively depend upon these methods but, from the organic chemist's point of view in the first instance, study the *mechanism* of the reactions of polymerisation, and determine the quantity and the structure of the products of polymerisation. In many cases it has been found that the process of polymerisation of unsaturated hydrocarbons, in particular conditions, *taken as whole*, is not a simple chain reaction; at least two processes take place simultaneously. For instance, in the case of polymerisation by heat of

<sup>18</sup> *Trans. Faraday Soc.*, 1935, **31**, 875.

<sup>19</sup> *J. Chem. Physics*, 1935, **3**, 402.

<sup>20</sup> *Trans. Faraday Soc.*, 1935, **31**, 875.

isoprene and methyl isoprene at temperatures above  $150^{\circ}\text{C}$ . the reaction proceeds according to the following scheme :—

At higher temperatures, *i.e.*, at  $200^{\circ}\text{C}$ ., the dimer begins to polymerise, and the product of polymerisation is, therefore, a mixture of compounds which do not belong to the same homologous series. The ratio of dimer to polymer in the case of methyl isoprene (at  $150^{\circ}$ ) is 2 : 2 : 1.<sup>21</sup>

If we assume that the process of polymerisation (in analogous cases) is a chain reaction, and base our calculations on this assumption, it might easily happen that the conclusions arrived at have nothing to do with the facts of the case.

**Dr. G. Salomon (Zurich)** said: I would like to mention once more the great difficulties in understanding the mechanism of "slow" reactions. As is well known, several factors may influence the rate of reaction, so in many cases we have no means of deciding which of these has the mayor effect. There are two extremely different types of "slow" reactions: radical association and amino condensation.

For the first type the association itself is slow and there should be no solvent effect. On the other hand from my own experiments it seems very probable that amino condensation is a normal reaction, only retarded by organic solvents. It will be necessary to investigate the lifetime of the unactivated amino halogen alkyl complex in different solvents to decide the real cause of these abnormalities. If there is a connection between the solubility of the compound formed and the rate of reaction then the number of  $\text{CH}_2$ -groups in the reacting molecules should also influence the rate. For example cyclo-hexadecamethylenimine hydrobromide is readily whereas piperidine hydrobromide is only slightly soluble in benzene.

It is moreover obvious that an intermediary change of valency in the nitrogen atom may also influence the reaction; but it does not seem possible to express this change in a more quantitative manner.

**Dr. C. E. H. Bawn (Manchester)** said, *in reply to Professor Mark*: It is to be expected, as pointed out by Evans and Polanyi,<sup>22</sup> that the collision number in solution may be as large as  $10^{12}$  (the corresponding value for gaseous reactions being  $10^9$ - $10^{10}$ ). This increase, together with a decreased activation energy (which will be dependent on the solvent) may account for the increased reaction rates in solution, especially in simple cases such as the bimolecular polymerisation of ketene.<sup>23</sup>

*In reply to Dr. Mochelvy-Hughe*: (a) The formation of high molecular weight polymers was considered as occurring by a series of consecutive bimolecular reactions. The transition state method was used to evaluate the steric factor of these (bimolecular) reactions and was not applied to the reaction as a whole. A knowledge of these separate bimolecular constants suffices to calculate the total rate and to allow of certain conclusion regarding the final chain reaction.

(b) It is assumed in evaluating the partition function for the transition state that the vibrations are harmonic. This is admittedly an approximation which seems to be good for normal molecules,<sup>24</sup> and leads directly to the conclusion that the intermolecular motions are independent of each other. If this condition does not apply then it is not possible to evaluate the partition function. By making this assumption it may be shown that

<sup>21</sup> For particulars, see: P. N. Kogerman, *Additionsreaktionen und Polymerisation des 2, 3-Dimethylbutadiens*, Sitzungsber. d. Naturforscher-Gesellschaft bei der Universität Tartu, Band XLI, 1934.

unimolecular dissociations follow the rate-law  $k = ve^{-E/RT}$  which we know is closely obeyed. This relationship was used in arriving at the results of Table I.

(c) The transition state is defined by a co-ordinate<sup>25</sup> which is tangential to the reaction path at the top of the potential barrier. It follows, therefore, that  $\frac{dV}{dt} = 0$  at the transition state, and, thus the force will be zero.

## POLYMERISATION IN MONOLAYERS.

By GEOFFREY GEE.

*Received 10th July, 1935.*

### Polymerisation in Monolayers.

The purpose of the present communication is to describe briefly an investigation of the polymerisation of drying-oils accompanying the process of "drying" when the material is spread as a unimolecular film on the surface of water or dilute acid.

No complete agreement has been reached as to the mechanism of the drying of oils, and in particular the role of oxygen remains a matter of discussion, but all workers are agreed that polymerisation plays an important part in producing the final varnish film. Probably the largest body of opinion now regards the drying process as consisting of an oxidation of the unsaturated linkages of the oil to peroxides, which subsequently polymerise.<sup>1, 2</sup> It will be shown that a mechanism essentially similar to this gives a complete and self-consistent explanation of the experiments which are described below.

### Experimental Methods.

The material employed in the investigation was the maleic anhydride compound of  $\beta$ -elaeostearin described by Morrell.<sup>3</sup> We are indebted both to Dr. Morrell and to the British Dyestuffs Corporation for specimens which gave similar results. Unimolecular films were spread from benzene on a trough of  $N/100$   $H_2SO_4$ , and provision was made for the simultaneous measurement of surface pressure—by means of a Langmuir torsion balance, and phase boundary potential. The trough was completely enclosed in a thermostated box and the apparatus so arranged that all measurements and adjustments could be made from outside.

The characteristics of a freshly spread film were entirely in accord with those to be anticipated from the formula proposed for this material by Morrell but it was found that the films were unstable and rapidly underwent a spontaneous reaction, accompanied by changes in both the surface pressure and potential. It is clear that these changes may be employed as the basis of a study of the reaction kinetics, and it has been found most convenient to work at constant pressure, measuring the area and potential at suitable intervals.

<sup>1</sup> Elm, *Ind. Eng. Chem.*, 1931, **23**, 88.

<sup>2</sup> Morrell, *Ind. Chem.*, 1925, **1**, 68; *J. Oil. Col. Chem. Assocn.*, 1929, **12**, 183, 1930, **13**, 84; *J. Soc. Chem. Ind.*, 1931, **50**, 27 T.

The reaction is found to be far from simple, but can be represented schematically as follows:

Here X represents the initial unsaturated glyceride, which first oxidises ( $k_1$ ) to a peroxide  $\text{XO}_2^1$ , which is however unstable and may react in either of two ways:

- (a) by polymerisation ( $k_2$ ), or
- (b) by isomerisation ( $k_3$ ) to a more stable body  $\text{XO}_2$ .

Finally, the latter may also polymerise ( $k_4$ ).

The product which is obtained on oxidation thus depends on the experimental conditions: at high pressure  $k_2 \gg k_3$  and the  $\text{XO}_2$  stage is not observed; while at low pressure  $k_3 \gg k_2$  and the  $\text{XO}_2$  formed remains stable unless the pressure is raised. By suitable adjustment of the conditions of temperature and pressure, the polymerisation of the two oxidised forms can be studied separately, as described below.

### Polymerisation of the Oxidised Oil.

The evidence that the final products obtained are polymeric in nature is derived in part from a consideration of the nature of the final film.

FIG. 1.

During the course of the reaction a fluid film of  $\beta$ -elaeostearin becomes converted into a continuous gel-like structure, while the maleic anhydride compound gives highly viscous products which break up on extension. It is suggested that the difference between these two cases arises from the greater ease of cross-linking between the molecules in the former. Further evidence of the nature of the process is given by the effects of the various kinds of positive and negative catalyst which have been employed (see below).

The simpler polymerisation process to investigate experimentally is the one represented above by the constant  $k_4$ . It will be clear from the foregoing that by carrying out the oxidation at a low pressure a film of pure  $\text{XO}_2$  can be produced if time is allowed for the isomerisation to be complete (10 to 15 minutes at 40 to 30° C.). If such a film be now compressed to a high pressure, polymerisation occurs and can readily be followed. Fig. 1 represents some typical curves of  $dA/dt$  plotted as

a function of the area per molecule  $A$ , and it will be noted that these curves are approximately parabolic in shape, but that the maximum is somewhat displaced towards the commencement of the reaction.

The polymerisation of the unstable peroxide  $\text{XO}_2^1$  can be approached in two ways. At low temperatures and high pressures  $k_2 \gg k_1$ , so that the whole process ( $\text{X} \xrightarrow{k_1} \text{XO}_2^1 \xrightarrow{k_2} \text{polymer}$ ) is pseudo-unimolecular; but at high temperatures and lower pressures this is no longer the case; the two processes can then be observed to proceed successively. Some representative velocity curves are given in Fig. 2, in which a separation of the lower pressure curves into two portions, of which the second is roughly parabolic in shape, is to be observed.

This method of investigation is limited to those special cases in which the values of  $k_1$  and  $k_2$  are within certain fairly narrow limits: the method now to be described is more generally applicable. If a film is spread and allowed to oxidise completely at low pressure the product will consist of a mixture of the two oxidised forms, the proportions of which will change progressively with time. Such a film may now be compressed, when the predominant reaction will be the polymerisation of  $\text{XO}_2^1$  ( $k_2$ ), which can therefore be followed. It is found that the stable material ( $\text{XO}_2$ ) present acts as an inhibitor at low temperatures, when it is evidently incapable of taking part in the polymerisation chain, but a correction can easily be applied by calculating the concentrations of  $\text{XO}_2$  in a series of films which have been oxidised for various lengths of time, and extrapolating the polymerisation constants to zero concentration. It is found that  $1/k$  is roughly a linear function of the  $\text{XO}_2$  concentration ( $c$ ) as would be anticipated from the well-known equation

$$k = \frac{k_0}{1 + \alpha c}.$$

Fig. 3 gives some velocity curves obtained in this way, and the same general shape is evidenced, but the displacement of the maximum towards the start of the reaction is now much more pronounced.

### Reaction Kinetics.

In seeking an interpretation of the shape of the velocity curves two distinct methods of approach have been employed. The first of these

FIG. 2.

is based on the analysis given by Semenov<sup>3</sup> of the induction period considered from the point of view of thermal gaseous chain reactions. The fraction  $\xi$  of the original material undergoing reaction in time  $\tau$ , reckoned from the time of half reaction, is given by

$$\xi = \frac{1}{1 + e^{-\phi\tau}} \quad (1)$$

where  $\phi$  is a function of temperature and pressure of the form

$$\phi = Bp^n e^{-\frac{K}{RT}} \quad (2)$$

For experiments with monolayers, in which  $A$  is the dependent variable we may put

$$\xi = \frac{A - A_0}{A_\infty - A_0} \quad (3)$$

FIG. 3.

where  $A_0$  and  $A_\infty$  are initial and final areas. It is then easily shown that

$$\frac{dA}{dt} = \frac{k_s}{A_\infty - A_0} (A_\infty - A)(A - A_0), \quad (4)$$

in which  $k_s$  is written for  $\phi$ . The plot of  $dA/dt$  against  $A$  required by (4) is clearly parabolic, a form which is closely approached by many of the experimental curves.

For the cause of the observed divergencies from the parabola we must consider an attempt which has been made<sup>4</sup> to analyse the kinetics of a polymerisation chain initiated by the slow primary activation of the monomer followed by the rapid reaction of the product with successive

<sup>3</sup> Semenov, *Z. physik. Chem.*, 1931, **B 11**, 464; *Physik. Z. der Sowjet*, 1933, **4**, 906.

<sup>4</sup> Gee and Rideal, *Trans. Faraday Soc.*, 1935, **31**, 969.

molecules of inactive monomer. If the mechanism is represented by the following equations it can be shown that the observed kinetics are derivable on the assumption that the chains are stopped only by an increasing steric factor.

The various constants may be expressed as functions of  $r$  in terms of a parameter  $K$ , a typical case which is considered being given by

$$k_{r+1} = K/r, \quad (5)$$

while  $k_1$  is included in the general scheme by putting

$$k_1 = \alpha n_0 K \quad (6)$$

where  $n_0$  is the original number of molecules present and  $\alpha$  is a numerical constant. The analysis which has already been given (*loc. cit.*) derives the reaction velocity in terms of the total number of molecules  $N$  present at time  $t$ , and is not therefore directly applicable to the present case. We require also some relation between the size of a polymer molecule and the area it occupies on the surface. Four possible laws have been investigated, but since all lead to essentially similar results, it will be sufficient for the present purpose to illustrate the method by considering the simplest case, in which the area  $A_r$  of the  $r$ -mer is given by

$$A_r = A_0 + r \cdot \Delta A \quad (7)$$

where  $\Delta A$  is a constant.

On this basis, it can be shown that the velocity equation takes the form

$$\frac{dA}{dt} = \frac{2\nu + 1}{\nu^2 \Delta A} K n_0 (A_0 - \nu \cdot \Delta A - A)(A - A_0) \quad (8)$$

where  $\nu$  is the mean chain length of that portion of the material which has polymerised at time  $t$ .

Two extreme forms of curve are predicted:

(a) If  $\nu$  be equated to  $\nu_\infty$ , its value at the end of the reaction, equation (8) takes the same form as (4) by putting

$$\frac{(2\nu_\infty + 1)Kn_0}{\nu_\infty^2 \cdot \Delta A} = \frac{k_s}{(A_\infty - A_0)} \quad (9)$$

Thus for a reaction in which the chain length of the polymer does not change greatly during the reaction, an approximation to the parabolic form would be anticipated, and this should be realised in practise for short chain processes.

(b) If  $\alpha$  is small it is easily shown that the reaction becomes pseudo-unimolecular, a form which we should therefore expect for long chain processes.

The observed forms of curves are thus readily explicable in terms of this kinetic treatment and we may note also that the most asymmetrical curves are those associated with the largest expansion during reaction, and therefore the longest chains [compare *e.g.*, Fig. 3].

The complete characterisation of the polymerisation rate in terms

of the chain initiation and propagation rates requires the separate determination of  $Kn_0$  and  $\alpha$  which can theoretically be derived from observations of the early stages of the reaction, for it can be shown that the initial slope of the "velocity curve" and the initial acceleration are given by:

$$\frac{d}{dA} \left( \frac{dA}{dt} \right)_{A=A_0} = \frac{1}{2} Kn_0, \quad (10)$$

$$\left( \frac{d^2 A}{dt^2} \right)_{t=0} = 2\alpha K^2 n_0^2 \Delta A. \quad (11)$$

$\Delta A$  may also be calculated from observations of the area ( $A_M$ ) and height  $\left( \frac{dA}{dt} \right)_{\max.}$  of the maximum of the velocity curve, but in practise it is found best to attempt only to obtain relative values of  $\alpha$  and  $Kn_0$ , since the constants of equations (10) and (11) are altered if equation (7) is replaced by one of the alternative possibilities.

Observations in the neighbourhood of the start of the reaction are necessarily difficult and subject to large errors, so that for most purposes it has been found preferable to characterise the whole reaction in terms of the single constant  $k_s$ . For this purpose equation (4) may conveniently be modified by introducing the conditions for the velocity to be a maximum, whence it is easily shown that

$$k_s = \frac{4 \left( \frac{dA}{dt} \right)_{\max.}}{A_\infty - A_0}. \quad (12)$$

This equation has been employed in deriving the polymerisation constants quoted in this communication.

Analysis of the results of a large series of experiments shows that there is a good general correlation between  $k_s$  and  $\alpha K^2 n_0^2$ , which can be expressed approximately by the empirical relationship:

$$k_s^2 \propto (Kn_0)^2 \propto (\alpha Kn_0). \quad (13)$$

This is dimensionally correct and appears to indicate that  $k_s$  furnishes a satisfactory measure of the combined initiation ( $\alpha Kn_0$ ) and propagation ( $Kn_0$ ) velocity constants.

### Effects of Temperature and Pressure.

The effect of temperature and pressure on the rate of polymerisation of  $XO_2$  is shown in Fig. 4, in which  $k_s$  is plotted as a function of the surface pressure  $F$  for three different temperatures. For the lower temperatures the variation with pressure is accurately represented by the equation  $k_s \propto F^3$  and this is confirmed by a further series of measurements on substrates containing a catalyst ( $CoSO_4$ ) so that the constants are larger. At  $40^\circ C$ . however we find an increase of  $k_s$  at lower pressures, a phenomenon which appears to be correlated with a phase change, condensed to expanded, occurring within the pressure range 8 to 12 dynes/cm. at  $40^\circ C$ ., but below it at  $30$  and  $35^\circ C$ . Measurements of the  $\bar{F}$ - $A$  characteristics of films of  $XO_2$  at various temperatures confirm this explanation.

The temperature coefficient and energy of activation can thus only be obtained from the highest pressure (12 dynes/cm.) measurements, in which the material is in the same phase at all temperatures. The observed constants lead to a value for the energy of activation of 20,000

Cals, so that the total variation of  $k_s$  with temperature may be written

$k_s = k_0 F^3 e^{-\frac{20,000}{RT}}$  which is of the same form as Semenoff's equation (2).

In addition to this effect on the rate of polymerisation, alteration of temperature and pressure also modify the chain length of the final product. Although it is not at present possible to give an accurate measure of this quantity we can readily determine the manner in which the chain length varies as the conditions are changed. This can be done in two independent ways:

(a) By observation of the total expansion accompanying the reaction. If the areas are referred to a standard pressure, the expansion will be greatest for the longest chains.

(b) By observation of the extent to which the maximum of the curve is displaced. If  $A_M$  is the area at which the maximum occurs we may define a quantity  $\rho$  given by

$$\rho = \frac{A_M - A_0}{A_\infty - A_0} \quad (14)$$

For a parabola  $\rho = 0.50$ , while for a reaction which approaches a uni-molecular form  $\rho \rightarrow 0$ . From the previous analysis, it follows that as the chain length increases  $\rho$  will decrease.

These two methods both lead to the conclusion that the chain length of the  $\text{NO}_2$  polymers increases with rise of pressure, but is almost independent of temperature over the range  $30\text{--}40^\circ\text{C}$ .

The effects of temperature and pressure on the polymerisation of the unstable peroxide  $\text{NO}_2^1$  are more complex. The temperature coefficient has been obtained from a series of measurements at a pressure of 8 dynes/cm., and leads to an approximate value for the energy of activation of 5000 Cals. The principal effect of increasing the pressure is to produce an increase in the size of polymer produced. Reference to Fig. 3 shows that there is a complete change in the shape of the curve, and it is evident that the total expansion is increased and that  $\rho$  [equation (14)] is diminished. It may be noted that rise of temperature also leads to an increase in the polymer size.

Fig. 3 shows that there is a complete change in the shape of the curve, and it is evident that the total expansion is increased and that  $\rho$  [equation (14)] is diminished. It may be noted that rise of temperature also leads to an increase in the polymer size.

### Positive and Negative Catalysts.

A study has been made of the effect of adding various catalytic materials to the aqueous solution under the film, and the results may be illustrated by reference to some experiments with cobalt sulphate and hydroquinone.

*Velocity constants for polymerisation of Stable Isomer.*

FIG. 4.

Two series of observations on cobalt substrates are worthy of mention. The first is based on experiments in which the oxidation and polymerisation of the glyceride proceed progressively, so that the polymerisation rate is separately determinable [*cf.* Fig. 2].

The following results were obtained in this way, for polymerisation at 26° C. and  $F = 5$  dynes/cm.:

Concentration of $\text{CoSO}_4$ . . . . .	$10^{-4}$	$5 \times 10^{-4}$	$2 \times 10^{-3}\text{M.}$
Velocity constant (mins. <sup>-1</sup> ) . . . . .	0.02	0.14	0.38

The second series gives the effect of cobalt on the rate of polymerisation ( $k_4$ ) of  $\text{NO}_2$  at  $F = 8$  and 30° C.:

Concentration of $\text{CoSO}_4$ . . . . .	0	$5 \times 10^{-4}$	$2 \times 10^{-3}\text{M.}$
Velocity constant (mins. <sup>-1</sup> ) . . . . .	0.05	0.17	0.33

In both cases a very large catalytic effect is observable. The first evidence of the inhibitory effect of hydroquinone is based on a somewhat different argument. In the course of a series of experiments on the effect of hydroquinone on the rate of oxidation at  $F = 11$  dynes/cm. and 2.5° C., it was found that small concentrations (up to 0.001 per cent. in the substrate) had no effect on the oxidation constant, but diminished notably the total expansion associated with the oxidation. Now under these conditions the reaction is essentially

and it is clear therefore that the hydroquinone is inhibiting the second stage of this process, *i.e.*, the polymerisation. Confirmation of this conclusion was obtained by allowing a film to oxidise and isomerise to  $\text{XO}_2$  at a low pressure and 35° C., and then injecting hydroquinone into the substrate so as to make the concentration 0.05 per cent. On subsequent compression to  $F = 12$  dynes/cm. no reaction was detectable in 20 minutes and thereafter proceeded very slowly, while in the absence of the inhibitor the entire polymerisation would have been complete in 30 minutes.

### Polymerisation of Mixed Films.

In the foregoing we have postulated as the final stage in the "drying" of glyceride films a polymerisation process proceeding by a chain mechanism, and perhaps the most direct proof of this conclusion is derived from experiments with mixed films. If the glyceride film be diluted by admixture with a stable ester, such as ethyl myristate we should anticipate that the latter, being unable to take part in the polymerisation chains, should act as an inhibitor. This conclusion is completely borne out by experiment, and reference may be made to Fig. 2, which gives the velocity of oxidation and polymerisation of a mixed film containing 10 per cent. of ethyl myristate at  $F = 9$  dynes/cm. Under these conditions the pure glyceride gives almost a linear curve but the retardation of the polymerisation produced by the ester causes the process to split into two fairly well separated consecutive reactions. It should be noted that addition of the ester has no effect on the rate of oxidation: there is indeed no apparent mechanism by which any such inhibition could be produced.

The study of the effect of esters on the polymerisation rate has been greatly extended, and in particular the polymerisation of the stable

isomer  $\text{XO}_2$  from numerous mixed films has been investigated. The esters employed have been selected so as to cover a considerable range of degrees of unsaturation, and include in addition to ethyl myristate, triolein, methyl linoleate, ethyl linolenate and methyl  $\beta$ -elæostearate. We are indebted to the British Dyestuffs Corporation for gifts of specimens of the three last named. It was anticipated that an unsaturated ester might prove capable of taking part in the polymerisation chains, so that the inhibitory efficiency would decrease with increasing unsaturation: this is in general confirmed.

Addition of an ester diminished both the rate of polymerisation and also the final complexity of the polymer. This latter conclusion has to be based mainly on the shape of the curves, and the values found for  $\rho$ , since there is an inevitable uncertainty in interpreting the areas of mixed films. Variations in the total expansion are therefore not necessarily due to changes in the polymer size.

Thanks are due to Professor E. K. Rideal, the instigator of this work, for much helpful advice and criticism, and to the British Dyestuffs Corporation for material and financial assistance.

### Summary.

An account is given of experiments on the "drying" of monolayers of the maleic anhydride compound of  $\beta$ -elæostearin on water, and a mechanism is proposed which recognises the possible existence of two oxidation products of different stability. The polymerisation of both is described and the energies of activation are found to be 5,000 and 20,000 Cals.

It is shown that the observed shapes of the velocity curves can be completely accounted for by assuming that polymerisation proceeds by a chain mechanism in which the chains are terminated by a steric factor.

Two classes of positive and negative catalyst are considered, these being added (*a*) to the substrate and (*b*) to the film. In the latter class are a series of esters, which inhibit polymerisation, by breaking the chains, this effect being most marked with a completely saturated ester.

## THE POLYMERISATION OF GASEOUS FORMALDEHYDE AND ACETALDEHYDE.

BY J. E. CARRUTHERS AND R. G. W. NORRISH.

*Read in Summary on 27th September, 1935.*

In the course of experiments on the photo-chemical oxidation of formaldehyde by ultra-violet light of 3000 Å.U., it was found that a rapid reduction of pressure was induced by the light. This reduction of pressure continued on extinguishing the light, although the process of oxidation ceased. No such fall of pressure could be induced in the absence of oxygen. By a process of elimination the effect was traced to a polymerisation of the formaldehyde induced by the formic acid resulting from the photo-chemical oxidation. A similar polymerisation could be effected by the addition of traces of ozone to the formaldehyde in the dark, and here again formic acid was responsible.

It was then found that the addition of a few per cent. of formic acid in the dark to gaseous formaldehyde at about 500 mm. pressure induced a rapid polymerisation, the velocity of which was some hundred-fold greater than in the case of pure formaldehyde. The results indicate that we have here a promoter for the reaction in the gas phase enormously more powerful than anything which has hitherto been described. In the present paper we have undertaken a study of the kinetics of the process, and it is evident that we have to deal with a branching chain mechanism, in which both the initiation and branching of chains are dependent upon the formic acid. The process, however, is confined to the surface of the vessel, and we are thus concerned with the kinetics of a chain reaction in a heterogeneous system. It is interesting to note <sup>1</sup> that Spence has concluded that the polymerisation of liquid monomeric formaldehyde occurs by way of a chain reaction at a heterogeneous surface, and can in certain cases become explosive. In his case curious threadlike growths of the polymer developed at the surface of the vessel, and in our own case we have noticed similar formations.

FIG. 1.

The polymer itself has the physical properties of the polyoxymethylenes described by Auerbach,<sup>2</sup> and it is readily depolymerised by heating. We conclude that it has the essential structure suggested by Staudinger, for there is little doubt in view of the easy depolymerisation that the formaldehyde units are joined through oxygen atoms rather than by C—C linkages. Staudinger has shown how molecules of polyoxymethylene in aqueous media may increase in length by a chain process catalysed by hydroxyl groups or hydrogen ions; our own results suggest that in the case of the gas, similar polyoxymethylene chains can be built up at the surface, and that for this process the formic acid is a powerful promoter. Its exceptional efficiency operates through its power of producing branching chains, and we shall show in the discussion below that this conception is in full accord with the theory of Staudinger. Similar results have been obtained for the polymerisation

<sup>1</sup> *J.C.S.*, 1933, 1193; 1935, 506.

<sup>2</sup> *Arb. Kais. Gesundh.*, 1907, 22, 584, etc.

of acetaldehyde by formic acid, and the polymerisation of formaldehyde by acetic acid, though in the case of mixtures of acetaldehyde and acetic acid no effect could be observed. With glyoxal and formic acid the process appeared to stop short with a simple addition reaction between the two molecules.

### Experimental.

The first apparatus used is shown in Fig. 1. The reaction vessel consisted of a double-walled quartz tube of 130 c.c. capacity containing a quantity of water in the outer jacket, which was kept boiling by heating electrically. The inner vessel was attached by a ground glass joint to a mercury manometer and a tap leading to supplies of formic acid and

FIG. 2.

formaldehyde and to a mercury pump for evacuating. The formic acid was prepared by the standard method of H. Erdmann<sup>3</sup> and kept at room temperature in the liquid condition. The formaldehyde was prepared by the method of Trautz and Ufer<sup>4</sup> and stored in a trap surrounded by liquid air. Before use the formic acid was evacuated several times at  $-78^{\circ}\text{C}$ . (mixture of solid carbon dioxide and ether) to remove all traces of air. The connecting tubing up to the reaction vessel and the manometer was wound with nichrome wire and asbestos tape and kept electrically heated to about  $90^{\circ}$ . The manometer itself was similarly wound with nichrome wire and protected by a concentric glass tube and heated to the same temperature.

<sup>3</sup> *Vorlesung Vorparative Chemie II*, Stuttgart, 1923, p. 101.

<sup>4</sup> *J. prakt. chem.*, 1920, 105.

The taps and ground joint were lubricated with Apiezon grease "N" and were the only parts of the apparatus that remained cool. In order

Fig. 3.

It is seen that an enormous increase of velocity was observed at pressures of formic acid approaching 35 mm.

### Series II.—Estimation of Formic Acid during the process of Polymerisation.\*

A series of experiments was carried out starting with 500 mm. of formaldehyde and a fixed amount (30 mm.) of formic acid. The contents of the reaction vessel were condensed into a detachable liquid air trap at different stages of the reaction. This was then removed and water added; the resulting solution of formic acid was titrated with *N*/100 soda, using phenolphthalein as indicator. A blank run with pure formic acid showed that 30 mm. were equivalent to 14.1 c.c. of *N*/100 soda. In Table I. the results are shown and from

TABLE I.

Pressure of Formaldehyde.	Volume of <i>N</i> /100 Soda Required.	Pressure of Formic Acid.
400 mm.	14.1 c.c.	30 mm.
296 mm.	10.65 c.c.	22.6 mm.
224 mm.	8.2 c.c.	17.5 mm.
108 mm.	4.2 c.c.	8.9 mm.
9 mm.	3.8 c.c.	8.0 mm.

\* The results described in this section correct an error in our preliminary note. (*Nature*, 1935, 135, 582.)

to carry out an experiment the whole apparatus was first evacuated, formic acid was introduced to the desired pressure and then the formaldehyde.

### Series I. Reaction Rates.

The pressure of formaldehyde was fixed at 500 mm. and the rates of polymerisation observed for pressures of formic acid from 0.35 mm., the upper limit being fixed by the vapour pressure of the formic acid. Readings were taken every few minutes; results are shown in Fig. 2.

In Fig. 3 are plotted the reaction rates during the period of reaction corresponding to a pressure change of 500-400 mm.—as a function of the pressure of formic acid.

the plot in Fig. 4, it will be seen that there is nearly a linear relationship between the pressure of formic acid and of formaldehyde during the whole course of the polymerisation.

FIG. 4.

### Series III.--Experiments with Completely Heated Vessel.

The apparatus used for the experiments of Series I. and II. contained a stopcock and a ground joint connecting the quartz reaction vessel to the

FIG. 5.

glass portion of the apparatus. Neither of these parts could be directly heated and it was observed that the polymer separated at the cold part.

Experiments were now carried out in a completely heated system

(see Fig. 5), so that it was possible to assess the importance of these cold portions of the apparatus. The difficulty of the ground joint was overcome by using a system made entirely of glass, but there still remained

FIG. 6.

the problem of the cold part in the neighbourhood of the stopcock. The device illustrated in Fig. 6 provided a solution. The principle was to have a thread of hot mercury from the tap A up to the gas in the capillary leading to the reaction vessel. This eliminated all the cold portions of the apparatus.

FIG. 7.

The method of operation of the mercury "cut-off" was as follows: first of all the reaction mixture was introduced into the reaction vessel in the usual way, through tap A,—tap B being closed. A was then closed and by opening B, a thread of mercury allowed to enter the capillary BDE. The small amount of gas trapped in AD was removed by the

pump on carefully opening A.

In the completely heated system no polymerisation took place in 300 mm. of formaldehyde, even when 32.4 mm. of formic acid were present. It was first thought that this stability was possibly due to the fact that the vessel was new and consequently that the surface was not

"matured." The reaction vessel was allowed to cool slightly, thus depositing a layer of polymer on the surface. On introducing more formaldehyde, however, there was practically no polymerisation.

A further experiment in which the hot vessel was packed with quartz and glass tubing similarly showed no polymerisation.

These experiments led us to the view that the polymerisation observed in experiments with formaldehyde required the presence of a cold surface where the polymer could be deposited.

#### Series IV.—Vessels with Cooled Surfaces.

Construction of new types of reaction vessels enabled the influence of a cooled surface to be tested.

In A, Fig. 7, cooling was effected by a flow of cold water, in a manner seen from the diagram, the area of cooled surface being about 10.5 sq. cms. The whole of the other portion of the reaction vessel was heated to 100°C by immersion in boiling water, and the tubing heated electrically as before. The procedure was to introduce the gas into the hot reaction vessel, and then to turn on the cooling water after the initial reading of pressure had been observed.

Fig. 8 shows the results of experiments carried out with this cooled surface. The decrease of pressure, due to cooling of the gas when the cold surface is introduced at the beginning is small—as is seen for example, in curve 1 of Fig. 8.

The important observation arising from these experiments is that although we have a considerable area of cold surface and although the initial rate of polymerisation is very rapid, yet the pressure does not fall to zero. This means that in this case we must have an equilibrium between formaldehyde gas and polymer. The position of the equilibrium depends on the pressure of formic acid present, being more and more in favour of polymerisation as the pressure of formic acid is increased.

When, however, an element of volume of the system, adjacent to the surface was cooled as in B (Fig. 7) in which a section of the capillary was kept cool with water, or in C (Fig. 7) in which a small cooled space P was provided in the centre of the reaction vessel it was found that the polymerisation was complete and no equilibrium was observed. From this we may conclude that if the cooled surface is in contact with the hot gas, partial depolymerisation leading to equilibrium occurs but that if the

FIG. 8

cooled surface be in contact with cold gas there is no depolymerisation and the reaction proceeds to completion.

### Series V.—Experiments at 18° C.

Experiments at room temperature have shown that the promoting influence of formic acid is as strongly marked at 18° C. as at 100° C. The rate of polymerisation of the pure gas is greater at the lower temperature but even so, the reaction rate is tremendously accelerated when 21 mm. of formic acid are added to 400 mm. of formaldehyde (see Fig. 9) and polymerisation is complete in forty minutes.

In these experiments the reaction vessel only was maintained at 18° C., the connecting tubing and manometer being heated electrically as before.

**Examination of the Polymer.**—The polymer which is deposited either at 18° C. or at 100° C. is a white powder insoluble in water on heating, and insoluble in alcohol and ether. The solid melts over a range of temperature, the mean being about 157° C.

It appears to be of similar nature to the insoluble polyoxymethylenes described by Auerbach<sup>2</sup> and Staudinger.<sup>3</sup>

#### Order of Reaction.

—An analysis of the data represented in the curves of Figs. 2 and 8 shows that the polymerisation reaction both with the vessel at 18° C. and also at 100° C. is approximately of the second order. Examples are given in Table II, where the concentrations are expressed in mm. for calculation of  $k_{19}$ .

The bimolecular constants have been calculated from point to point in the curves. These results when coupled with the data of Series II

FIG. 9.

are of peculiar interest when it is remembered that the pressure of formic acid is falling progressively throughout the run. Its significance will be seen in the discussion of the kinetics below.

### Series VI.—Polymerisation of Gaseous Acetaldehyde.

In view of the action of formic acid on the polymerisation of formaldehyde, experiments were carried out in an attempt to find if an analogous reaction occurred in the case of acetaldehyde. Observations were made both at 100° and 20° using reaction vessel B (Fig. 7). It was found at 100° C. formic acid had no effect on acetaldehyde. At 20° however, there

\* Time (minutes); *t* = Pressure (mm.);  $k = p \cdot k \cdot 10^5 \pm 5$ .

was a rapid polymerisation showing a striking similarity to that found with formaldehyde. At this temperature pure acetaldehyde vapour was completely stable, while the addition of formic acid up to about 25 mm. pressure caused a rapid polymerisation. With a packed vessel the rate of polymerisation was still greater. Results are shown in Fig. 10. The increase of reaction velocity in the packed vessel is roughly in proportion to the increase of surface and it is apparent that the polymerisation of acetaldehyde is again a heterogeneous reaction.

Although the effect of the formic acid is numerically not quite so great in the case of acetaldehyde as it is with formaldehyde, yet the curves of Figs. 3 and 10 are of the same form and in acetaldehyde we see the same tendency for a very rapid increase in the rate of polymerisation as the pressure of formic acid reaches a limiting value.

### Series VII. Experiments with other Substances.

The effect of water and acetic acid on the polymerisation of formaldehyde at 100° C. was measured in the apparatus used in Series I., and the results are shown in comparison in Fig. 11. It will be seen that whereas the acetic acid produces an induced polymerisation of the same order of magnitude as formic acid, the effect of water is very small. On the other hand, experiments with acetaldehyde, show that acetic acid has no observable polymerising effect either at 100° C. or 20° C.

**Series VIII.—Experiments with Glyoxal.**

Using monomeric glyoxal prepared by the method of Harries and Temme<sup>6</sup> it was found that glyoxal in the presence of formic acid in the

FIG. 10.

rate of polymerisation as a function of the pressure of formic acid is characteristic of a chain reaction. As the pressure of formic acid approaches 35 mm., the velocity increases in such a manner as to suggest that the reaction is about to become explosive. The form of the curve can be represented by the empirical relation :

$$\text{Rate} = \frac{A(\text{H. COOH})}{B - (\text{H. COOH})}$$

This is seen by reference to Table III.

From the experiments recorded in Series II, however, it will be seen that the disappearance of the formic acid is closely related to the disappearance of the formaldehyde,

vapour state does not exhibit the phenomenon of induced polymerisation shown in the case of formaldehyde but that it appears to form a condensation product directly with the formic acid. Thus by addition of excess of glyoxal to formic acid a rapid reduction of pressure occurred and the pressure of glyoxal then remained unchanged. The experiments were not prosecuted in detail but it appeared that the two substances reacted in about equimolecular proportions.

**Discussion.****Kinetics of the Reactions.**

The curve shown in Fig. 3 for an approximately fixed concentration of formaldehyde representing the

<sup>6</sup> Ber., 1907, 40, 105.

and that at all times during the reaction an approximately constant ratio is maintained between the concentrations of the two substances. Further, an investigation of the order of reaction throughout the course of a given run shows that the polymerisation remains bimolecular with reference to the formaldehyde.

The interpretation of these facts may be readily obtained if it be assumed that the polymerisation occurs at active centres generated (1) by a primary process dependent upon the reaction of formaldehyde with formic acid in the gas phase (2) by a branching process arising from the encounter between formic acid and an already existing centre, and extinguished by their reaction with formaldehyde.

Thus, writing  $n$  for the stationary concentration of centres we obtain

$$\frac{dn}{dt} = k_1(\text{acid})(\text{ald}) + k_2n(\text{acid}) - k_3n(\text{ald}) = 0.$$

Whence

$$n = \frac{k_1(\text{acid})(\text{ald})}{(k_3)(\text{ald}) - k_2(\text{acid})} \quad (1)$$

FIG. 11.

The rate of polymerisation of aldehyde is given by  $k_3n(\text{ald})$ .

$$\text{Whence} \quad -\frac{d(\text{ald})}{dt} = \frac{k_1k_3(\text{acid})(\text{ald})^2}{k_3(\text{ald}) - k_2(\text{acid})} \quad (2)$$

This equation is in agreement with the empirical expression obtained from the results of Series I for a constant pressure of formaldehyde.

Assuming that a molecule of formic acid disappears at each formation of a new chain, by the branching process and ignoring the comparatively small removal by the primary reaction, the rate of loss of formic acid is given by

$$\begin{aligned} -\frac{d(\text{acid})}{dt} &= k_2n(\text{acid}) \\ &= \frac{k_2k_1(\text{acid})^2(\text{ald})}{k_3(\text{ald}) - k_2(\text{acid})} \quad (3) \end{aligned}$$

Dividing equation (2) by equation (3), we obtain

$$\frac{d(\text{ald})}{d(\text{acid})} = \frac{k_3(\text{ald})}{k_2(\text{acid})} \quad (4)$$

Whence by integration

$$(\text{ald}) = C(\text{acid})^{k_3/k_2},$$

and thus that if

$$\begin{aligned} k_3 &\sim k_2 \\ (\text{ald}) &= C(\text{acid}) \end{aligned} \quad (5)$$

in accordance with the results of Series II.

By combining expressions (2) and (5) for any one particular run, we obtain

$$-\frac{d(\text{ald})}{dt} = \frac{k_1 k_3}{k_3 - k_2} (\text{ald})^2.$$

Thus it follows that the order of the polymerisation reaction is approximately bimolecular in accordance with the data of Tables II. and III.

From the experiments of Series III. in a completely heated system, it is clear that the rate of depolymerisation is greater than that of polymerisation, for no fall of pressure could be observed even with packed vessels and high pressure of formic acid. Upon the introduction of a cooled surface, however, the polymerisation reaction immediately took place. If this cooled surface was exposed to the bombardment of the hot gas, partial depolymerisation occurred, and thus an equilibrium pressure was reached; but if the cooled portion was isolated in a side capillary, then in this part there was no depolymerisation, and reaction therefore proceeded to completion.

### Mechanism of the Process.

Staudinger has visualised the initiation of chains in aqueous solvents as dependent on the primary production of dihydroxymethylene from formaldehyde and water. The chains are propagated in the following manner, with the production of polyoxymethylenes.

We conceive that in our case the function of the formic acid is to generate in the gas phase a compound analogous to the dihydroxymethylene, namely the monoformic ester of dihydroxymethylene as represented by the equation:

From this, polymerisation chains can grow by the reaction of the hydroxyl group, and the product will separate at the cold surface of the vessel. This constitutes the primary process referred to above.

It will be observed, however, that instead of the addition of formaldehyde to the polymerising chain, an addition of formic acid may occur, and this process will produce two terminal hydroxyl groups.

From each of these hydroxyl groups a new chain of polymerisation can be propagated. In this way, we may visualise the branching mechanism referred to above, in which a formic acid molecule is removed by reaction with a centre of polymerisation and generates two new centres thereby.

If the probabilities of the fixing of formaldehyde and formic acid by the polymerisation process are roughly equal, the requirements of equation (5) are fulfilled. It will then follow that the pressure of formic acid remains approximately proportional to the pressure of formaldehyde throughout the course of a given run.

The extinction of the reaction centres was represented as dependent on formaldehyde in terms of an alternative reaction between the centre and an aldehyde molecule. This would occur if instead of the formation of an addition compound a condensation product were produced.

In this case the aldehyde group terminates the chain, which in the absence of the hydroxyl group, cannot be propagated further.

This mechanism faithfully conforms to the requirements of the kinetic hypothesis developed above. It represents the starting and branching of reaction chains as dependent on formic acid and their extinction dependent on the formaldehyde. In addition, it introduces into the mechanism of Staudinger for the formation of large polyoxymethylene molecules the possibility of the formation of branching chains. It is this fact which accounts for the enormous promoting activity of the formaldehyde, as compared with other polymerising agents which are only able to initiate straight chains, without the possibility of branching.

A process of this kind would tend to give rise to thread-like molecules, branching at intervals, and ultimately if the growth continued long enough to an intertwined network. This structure might be considered as a basis for the gel formation in monomeric liquid formaldehyde described by Spence.<sup>1</sup> In this connection, it is also of interest that Spence has described an apparent explosive polymerisation of the liquid, with evolution of heat. Such a process must undoubtedly occur by a branching chain mechanism, and on the above theory would be readily catalysed by the presence of formic acid. It is significant that Spence found that the stability of monomeric liquid formaldehyde depended upon its freedom from oxygen, and since the interaction of oxygen with formaldehyde undoubtedly tends to produce formic acid, it is tempting to conclude that the stability of the liquid is in effect bound up with its freedom from formic acid.

The rapid polymerisation of formaldehyde by acetic acid and of acetaldehyde by formic acid (Series VI. and VII.) has been shown to be apparently identical with the polymerisation of formaldehyde by formic acid. It will be seen that simply by the substitution of  $\text{CH}_3$  for  $\text{H}$  in the formulæ, the kinetics of these reactions may be explained by an entirely analogous mechanism to that developed above. No polymerisation, however, is induced by acetic acid in acetaldehyde, and it may be concluded that the first stage in the chain is unable to take place, and that there is no tendency to form an addition compound between acetaldehyde and acetic acid. With glyoxal, on the other hand, some sort of compound with formic acid is clearly formed, but there is no propagation of a reaction chain, a circumstance which might be explained by the absence of a hydroxyl group in the structure of the product. The matter, however, awaits further investigation.

### Summary.

1. It is shown that the polymerisation of monomeric formaldehyde vapour both at  $100^\circ$  and at  $18^\circ \text{C}$ . is subject to a marked promotion by the presence of relatively small quantities of formic acid.
2. As the pressure of formic acid is increased the rate of polymerisation at  $100^\circ \text{C}$ . increases to such an extent as to indicate that it will become infinitely large at pressures of formic acid beyond about 40 mm.
3. The formic acid disappears during a given run at a rate which throughout is nearly proportional to the rate of removal of formaldehyde.
4. During a given run the polymerisation is bimolecular with reference to the formaldehyde.
5. With a vessel completely heated to  $100^\circ \text{C}$ . there is no polymerisation, even with 30 mm. of formic acid.
6. The process is heterogeneous and occurs at some element of cold surface. If the cold surface be surrounded by a volume element which is also cold, the polymerisation goes to completion. If, however, the cold surface be exposed to the bombardment of the hot gas there is sufficient depolymerisation to cause an equilibrium. When the whole surface is at  $100^\circ \text{C}$ . the rate of depolymerisation is so much greater than the rate of polymerisation that there is no measurable reaction.
7. Similar results are obtained with formaldehyde and acetic acid, and acetaldehyde and formic acid, but with acetaldehyde and acetic acid, and glyoxal and formic acid there is no polymerisation.
8. The above results are explained on the basis of a branching chain mechanism in which the formic acid is responsible both for starting and branching the chains, while the extinction of chains occurs by an alternative reaction with formaldehyde.
9. The process may be visualised by an extension of the theory of Staudinger in which polyoxymethylene chains originate from the hydroxyl group of the formic acid. The high efficiency of the formic acid as a promoter is then explained by its addition to the polyoxymethylene chain, with the production of two hydroxyl groups and consequent branching.
10. The bearing of these results on the polymerisation of monomeric liquid formaldehyde is discussed.

# RECENT INVESTIGATIONS INTO THE DRYING OF OILS AND RELATED UNSATURATED COMPOUNDS.

BY R. S. MORRELL AND W. R. DAVIS.

The chemical and physical changes that occur during the drying of an oil can be studied with greater accuracy in pure compounds of suitable structure than in the complex mixture of glycerides found in the natural oil.

Two classes of complex formed from maleic anhydride and  $\alpha$  and  $\beta$  elæostearic acids and their two respective triglycerides have recently been the subject of an investigation which has thrown further light on the "drying" process. A preliminary observation that the maleic anhydride compound of  $\beta$  elæostearin would set to a hard film in about twelve hours at room temperature or one hour at  $100^{\circ}$  C., whilst the corresponding maleic anhydride compound of  $\alpha$  elæostearin remained fluid for several weeks, suggested these compounds as a profitable field of investigation.

Combination between maleic anhydride and  $\alpha$  and  $\beta$  elæostearic acids or their triglycerides can be carried out quantitatively to give compounds of the following structure.<sup>1</sup>

$\alpha$  elæostearic acid maleic anhydride compound.

$\beta$  elæostearic acid maleic anhydride compound.

It is of interest to note that with  $\alpha$  and  $\beta$  elæostearic acids two possible combinations with maleic anhydride exist for each isomer. Since the acid contains three conjugated double bonds either of two pairs might react with maleic anhydride according to the Diels-Alder system.<sup>2</sup> Actually only one combination product is formed for the  $\alpha$  acid and one for the  $\beta$  acid, there being no experimental evidence for the existence of mixtures. Examination of the atomic models of the

<sup>1</sup> Morrell and Samuels, *J.C.S.*, 1932, 2251.

<sup>2</sup> Cf. Farmer, *Ann. Reports Chem. Soc.*, 1930, 88.

eight possible *cis* : *trans* isomers of this acid shows that on the assumption that stearic hindrance occurs due to the terminal hydrocarbon chains, the carboxyl groups and the hydrogen atoms, the following types of combination are favoured structurally:—

<i>Isomers of elæostearic acid</i> C = <i>cis</i> ; T = <i>trans</i> .	<i>Type of maleic anhydride</i> <i>addition compound.</i>
T. T. T.	Mixture of $\alpha$ and $\beta$ compounds.
T. C. T.	Mixture of $\alpha$ and $\beta$ compounds.
T. T. C.	$\alpha$ compound possible
C. T. T.	$\beta$ compound possible.
T. C. C.	$\alpha$ compound most probable.
C. C. T.	$\beta$ compound most probable.
C. T. C.	No reaction likely.
C. C. C.	No reaction likely.

In the above table an  $\alpha$  compound (I) is designated as one in which the two ethenoid linkages most remote from the carboxyl radical are involved in the reaction and a  $\beta$  compound (II) that in which the two near to the carboxyl radical react.  $\alpha$  and  $\beta$  elæostearic acids give, therefore, typical  $\alpha$  and  $\beta$  maleic anhydride compounds respectively and on this evidence the  $\alpha$  acid is probably of T. C. C. and the  $\beta$  of C. C. T. structure.

Oxidation experiments have been undertaken with solutions of these compounds whereby the amount of oxygen absorbed by the compound was followed conjointly with determinations of peroxide value, iodine value and viscosity, the last being a means of following the association of the oxidised molecules. The final oxidation product, after isolation from the solvent, was subjected to a more exhaustive chemical examination to confirm the structure of the oxidised molecule.

The choice of a suitable solvent as a medium for these experiments became a matter of great importance. Preliminary work showed that the amount of association consequent upon oxidation was closely related to the polarity of the solvent. Polar solvents were shown to restrict, whilst non-polar solvents favoured, molecular aggregation and in liquids of low dielectric constant, such as carbon tetrachloride and benzene, the majority of the oxidation product was precipitated as a gel within a few hours of oxidation. Glacial acetic acid and certain polar solvents, however, restricted the aggregation sufficiently to maintain a soluble polymer, glacial acetic acid being the most favourable for experiment. From the experiments in non-polar solvents was revealed the property of a precipitated gel to carry down with it any metallic catalyst used to assist oxidation. The oxidation process invariably came to a standstill after an oxidised gel had been precipitated and only recommenced on further additions of catalyst. Whether chemical or physical forces are responsible for this addition of the catalyst to the gel has not been decided, but adsorption forces would seem to be indicated.

Oxidation in benzene solution could only be carried out when catalysed, cobalt salts being the most suitable for this purpose. Oxidation in glacial acetic acid proceeded without the aid of a catalyst and only towards the end of the oxidation was the presence of a cobalt "drier" advisable to complete the oxygen absorption. It would seem as though in benzene the molecules were so oriented at the liquid gas interface as to have their reactive centres buried in the liquid away from the oxygen and one of the functions of the catalyst was to redispense this arrangement. This orienting influence of metallic bodies is considered by P. Slansky<sup>1</sup> where he advances the theory that basic catalyst such as lead oxide will draw the

<sup>1</sup> *Chem. Umschau*, 1924, 31, 277.

glyceryl radical of a surface molecule inwards towards the body of the compound thereby exposing the unsaturated acid chains to oxidation at the surface. In contrast is the function of carbon black, which becomes adsorbed on the unsaturated acid chains and holds them inwards away from the surface and in consequence reduces the amount of oxidation.

The so-called autocatalytic oxidation was noticed in all the experiments and the oxygen absorption/time curves were of the usual type for this process.

The final oxidation products of the  $\beta$  compounds (acid and glyceride) were such that both ethenoid linkages acquired two atoms of oxygen each. These two oxidised linkages were nevertheless markedly different in character, that in the aliphatic chain section of the molecule being peroxidic in structure, while that in the hydrobenzene ring showed a tautomeric equilibrium mixture of keto-hydroxy and di-hydroxy forms, *i.e.*

The formula of completely oxidised  $\beta$  elastearic acid maleic anhydride compound is

The oxidised glyceride has a corresponding structure,

From examination of the graphs of the oxidation process the peroxide radical appeared to be mainly, if not solely, responsible for the molecular association. The curve in Fig. 1 shows how the final equilibrium condition of the oxidised solution of  $\beta$  elastearin maleic anhydride compound in glacial acetic acid was reached by way of related changes in unassociated peroxide content and viscosity. As the unassociated peroxide content fell, i.e., the peroxides associated, the viscosity rose until a final equilibrium condition was reached concurrently in both properties.

The  $\alpha$  acid compound confirmed the hypothesis that the peroxide radical was solely responsible for association at ordinary temperatures. Here, only the ethenoid linkage in the aliphatic chain would oxidise, the product being of ketohydroxy structure ( $-\text{CO}-\text{CH}(\text{OH})-$ ) and unassociated. No peroxide could be detected. The absence of molecular association was amply evidenced from (1) the unchanged viscosity of the oxidised and unoxidised solutions, and (2) molecular weight determinations by the cryoscopic method on the isolated oxidation product.

The structure of the oxidised  $\alpha$  acid compound is :

The triglyceride has a corresponding structure.

The stability of the peroxide radical in the  $\beta$  glyceride compound, when produced at ordinary temperatures in non-polar solvents, is notable. The peroxide value remained unchanged at the theoretical figure for one peroxide grouping per molecule for 12 months. (The difference in the peroxide values of gels produced in polar and non-polar solvents is referred to later.)

The marked restriction that polar solvents have on the association of the oxidised  $\beta$  compounds has been mentioned on page 210; the influence of the solvent, however, extends further than the rate of association and has been shown to affect the properties of the gel formed.

The important connection between the fall in free peroxide content and the rise in viscosity, previously described, was only characteristic

of the association process when taking place in a polar solvent. Those gels, which were rapidly precipitated from non-polar solvents such as carbon tetra-chloride and benzene, gave a theoretical figure for one peroxide grouping at each of the "remote" chain ethenoid linkages and showed no such fall. It was clear, therefore, that the peroxide radicals in these rapidly formed gels were not combined in the same manner as those in the polymer- produced in polar solvents, and remained comparatively free. It is possible that in the complexes produced slowly in polar solvents, molecule is linked to molecule by primary valency forces operating at the peroxide radicals, such a combination not being broken down by the reagents used for estimating the free peroxide content, but later experiments have provided another explanation. Those gels, however, produced rapidly in non-polar solvents and precipitated as such, are of the character of molecular aggregations

in which polar forces or secondary valencies are the binding influence. The full complement of peroxide is given as a result of degradation of this polar aggregation by the reagents used in the peroxide estimation.

It is as yet too early to characterise in detail the nature of these secondary valencies, but evidence is accumulating from many sources to establish their importance in all types of resinification of which the drying oils and synthetic resins are but two classes.

Transition from polar aggregation to the true polymeric state is not effected easily at ordinary temperatures so far as the gels from the  $\beta$  maleic anhydride compounds are concerned, a characteristic indicated by the polar aggregations retaining their complement of free peroxide unchanged for 12 months.

Two series of observations may throw light on this transition from polar aggregates to true polymers. In the first series, the peroxidic polar aggregate from carbon tetrachloride was heated with glacial acetic acid at 100–110° C. for several hours. From the solution a brown amorphous substance was obtained whose peroxide value had fallen from 3.59 per cent. to 0.8 per cent. and on analysis showed a marked increase in the percentage of carbon. In the second series the same pale yellow gel was heated alone at 110° C. for six hours in an inert atmosphere after which the peroxide value had fallen to 0.39 per cent. Analysis of the brown gel gave a rise in carbon percentage which corresponded quantitatively to the loss of peroxide oxygen. The conclusion drawn is that on stoving a peroxide film of a drying oil, loss of active oxygen ensues and there is a linkage of molecules of the glyceride through the remaining oxygen atoms to form condensation polymers. The arrangement of these chains is as yet unknown. This association is of a different type to what occurs when a drying oil film sets at ordinary temperature to give peroxides, and may represent the character of such a film on stoving.

The slow fall in the peroxide value and the corresponding rise in viscosity as given in Fig. 1 may indicate that gradual decomposition of the peroxide occurs in glacial acetic acid, and associated oxides, possibly of a chain character are formed with an increase in viscosity of the solution. This aspect seems more probable than to put forward that chain polymers of peroxides are formed. This explanation would account for the improved durability of stoved films and for the gradual disappearance of "bloom," which has been shown to be dependent on the presence of peroxides.<sup>4</sup>

At ordinary temperatures the disappearance of the peroxide is very slow, and even at 100°–110° in glacial acetic acid is not complete after several hours' heating.

These results explain the difference in the drying time of the maleic anhydride compounds of  $\alpha$  and  $\beta$  elæostearin, and it seems clear that

<sup>4</sup> N. K. Adam and Morrell, *J.S.C.I.*, 1934, **53**, 255T.

in the drying of an unsaturated oil the position of the ethenoid linkages in the characteristic acid is of primary importance in deciding the speed with which a hard film is formed. Ethenoid linkages remote from a carboxyl radical oxidise to a peroxidic condition and in this form are responsible for the molecular association of the compound. Ethenoid linkages relatively near to the carboxyl radical oxidise to a non-peroxidic structure and do not contribute to the association in so far as ordinary temperatures are concerned.

It should be mentioned that the "remote" chain ethenoid linkage in the  $\beta$  compounds is by far the most active towards oxygen of any of the linkages in these compounds. B. Hughes<sup>5</sup> has examined films of these maleic anhydride compounds by surface potential methods and has shown that the induced polarity of the double bond in the chain can be traced from the anhydride radical. This induced polarity accentuates the intrinsic polarity of this bond in the case of the  $\beta$  compounds and depresses it in the case of the  $\alpha$ . Similarly the ring ethenoid linkages would be subject to the same influence, and the complete inactivity towards oxygen of the ring ethenoid linkage in the  $\alpha$  compounds is explained thereby.

The chemical and physical investigations of these compounds are therefore in agreement.

### Summary.

The combination of maleic anhydride and  $\alpha$  and  $\beta$  elæostearic acids and their corresponding glycerides has been investigated further.<sup>6</sup>

(1) Examination of the atomic models of the eight possible isomeric forms of elæostearic acid and a consideration of their reaction with maleic anhydride would assign to the  $\alpha$  elæostearic acid the arrangement of the three double linkages as T—C—C, and to the  $\beta$  elæostearic acid the form C—C—T.

(2) The oxidation of the maleic anhydride compounds of  $\alpha$  and  $\beta$  elæostearic acids and their glycerides has been studied. The influence of polar and non-polar solvents on the molecular aggregation of oxidation products was noted, and especially the action of oxidation catalysts in those media.

Only in the case of  $\beta$  elæostearic maleic anhydride compounds were peroxides produced at the remote double linkages. In the case of the  $\alpha$  compounds tautomeric keto-hydroxy compounds were formed and the ring double linkages were not attacked. In the case of the  $\beta$  compounds the ring double linkages were oxidised to the keto-hydroxy form. Association of the peroxide was shown to take place, but no association occurred in the case of the  $\alpha$  compounds or in the ring double linkages of the  $\beta$  varieties.

(3) The association of the peroxides formed in non-polar solutions is that of molar-aggregates due to the potential of the remote double linkage together with the addition of the strongly polar peroxide group.

In the polar solvents  $\beta$  compounds show association due to combination of primary valencies from the peroxide groups as indicated by the increase in the viscosity of the solution corresponding to a fall in peroxide value.

(4) The character of the associated "oxyns" has been investigated, especially the action of solvents on the associated "oxyns" and their behaviour on heating.

<sup>5</sup> *J.C.S.*, 1933, 338.

<sup>6</sup> Morrell and Samuels, *J.C.S.*, 1932, 2251; Morrell, Marks and Samuels, *J.S.C.I.*, 1933, 52, 130T.

It has been found that the peroxide oxyn formed at ordinary temperatures undergoes decomposition with loss of peroxide oxygen when heated either alone at  $110^{\circ}\text{C}$ . or in glacial acetic acid at the same temperature, indicating the formation of peroxide free condensation products. An explanation of the changes occurring during the stoving of drying oil films is advanced. It is probable that the slow fall in peroxide value accompanied by increase in viscosity in polar solvents is due to gradual decomposition of peroxide aggregates to give chain-like polymers of oxides; this would account for changes occurring in the ageing of drying oil films and in the disappearance of "bloom," which is ascribed to the presence of free peroxide groups.

(5) In view of the fact that the properties of the  $\beta$  elæostearin maleic anhydride compound are so similar to those of oil varnishes, especially Tung oil, and that it is possible to obtain these compounds in a pure form, it is hoped that many of the difficulties in investigating drying oil systems may be overcome. The results given in this and earlier communications favour such anticipations. The study of the oxidation has shown that the rate of oxidation as well as the character of the product are closely connected with the structure of the oil and especially with the position of the double linkages in its constituent glycerides.

(6) Of special interest is the observation of Hughes on the marked difference between the surface potentials of the  $\alpha$  and  $\beta$  maleic anhydride compounds, which shows how the polarity of the double linkages have increased or decreased by the attachment of the anhydride group.

(7) The valuable collaboration of Professor Rideal and Mr. Gee by their use of strictly physical methods has given results which correlate chemical and physical methods, so that the conclusions acquire a strength which either method alone would fail to obtain.

The study of the maleic anhydride compounds of other drying oils and their acids is in progress and it is hoped that further collaboration of chemical and physical methods will be possible.

The authors wish to thank the Government Grant Committee of the Royal Society and Messrs. Imperial Chemical Industries Ltd. for grants in aid of the research, and Professor W. N. Haworth, F.R.S., and the University of Birmingham, for providing facilities for carrying out the work.

### GENERAL DISCUSSION.

Dr. N. K. Adam (London) said: The evidence actually given by Mr. Gee in this paper seems to me insufficient to justify the view that the large increases in area which he has followed in detail are due to polymerisation, or combination between adjacent molecules in the film. It is evident that a rather complex reaction is occurring, but I suggest that, although polymerisation may be the cause of the gel-like elasticity observed in the final films, it is really oxidation which gives rise to the increase in area. My reasons for suggesting this are mainly that in all other known cases where oxidation of an unsaturated group in a hydrocarbon chain occurs at a point remote from the end group which forms the main anchorage to the water, the molecules tilt over at a greater angle to the vertical, thus occupying a larger area on the surface. It is not easy to see how mere combination between adjacent molecules would produce this increase of tilt and a larger area. The inhibitory action of hydroquinone on the increase of area seems to me most easily explained on the assumption that

it inhibits oxidation, not polymerisation. It may be, and probably is, the case that oxidation, once it has reached a certain stage, assists the polymerisation, but I would like to see much more evidence that the various reactions mentioned in the scheme at the beginning of the paper can be distinguished and studied separately. Perhaps Mr. Gee is in a position to give us some of this now.

**Professor K. H. Meyer** (*Genthod-Geneve*) said: It is well known that traces of superoxides accelerate the polymerisation of unsaturated compounds. Consequently any antioxidant such as hydroquinone which prevents the formation of superoxides inhibits also polymerisation.

**Mr. G. Gee** (*Cambridge*), in reply to Dr. Adam, said: The suggestion that the experimental results can all be interpreted on the basis of a series of oxidation processes is one which has already been carefully considered; but the conclusion which was reached is that no such mechanism is capable of giving an adequate account of the observations. There is, furthermore no *a priori* difficulty about the conception of a two-dimensional polymerisation process, and it is significant that Morrell and Davis working independently and by purely chemical methods on the bulk oxidation of the same material have arrived at a mechanism which does not differ significantly from the one presented here. A detailed account of the experiments is to be published shortly, but the evidence that we have to deal with true polymerisation processes may be summarised briefly here.

(i) The results of a very large number of reaction velocity determinations, showing excellent experimental agreement, demonstrate that the two processes identified as oxidation and polymerisation stages are entirely different kinetically; the effect of pressure on these two reactions is in the opposite sense, the oxidation being retarded and the polymerisation accelerated by rise of pressure. These observations are in complete accord with the retardation of surface oxidation by pressure found by Hughes and Rideal; and with the well-known accelerating influence of pressure on polymerisation in the bulk phase.

(ii) The effect of diluting the film with various esters—ethyl myristate, methyl linoleate, ethyl linolenate, and methyl  $\beta$ -elaeostearate—is difficult to understand on any basis other than the one given in the text. The film is not collapsed, and its area and potential (corrected for the contribution of the ester) are practically unchanged by the dilution. Furthermore, a simple change in orientation would be revealed by a change in the *oxidation* rate—this is not observed.

(iii) The observed area changes show that considerable molecular re-orientation must be involved. Now since the compression of the molecule under the conditions required for polymerisation is such that the double bond is already located in the surface, it is impossible to see how any major area changes could result from a simple oxidation. Study of a molecular model reveals that the formation of oxygen bridges between the oxidised double bonds—which are located immediately above the double ring systems formed by the maleic anhydride residues—must cause the molecules to incline outwards from the point of attachment. This distortion will necessarily result in the molecules occupying a larger area on the surface; and the expansion will increase rapidly with the growth of the polymer. This factor is probably important also in restricting the size of polymer which can be formed. It may be noted, in support of this view, that  $\beta$ -elaeostearin does not show these large expansions.

(iv) The physical characteristics of the final film are admitted by Dr. Adam to suggest the presence of polymers. It should be emphasised that the production of these viscous films is so intimately bound up with the extent of the expansion that one can only conclude that the area change is actually produced by the polymerisation.

(v) The inhibitory effect of hydroquinone is not surprising, as antioxidants are frequently inhibitors for polymerisation also; the mechanism of catalysed and inhibited polymerisation is as yet imperfectly

understood, and the fact that hydroquinone inhibits a reaction is no sufficient criterion on which to decide whether the reaction in question is oxidation or polymerisation.

**Dr. N. K. Adam** (*London*), in reply to discussion with Professor Kurt Meyer, *communicated*: The fact that hydroquinone sometimes inhibits polymerisation in bulk does not prove that the area increases in the monomolecular films are due to polymerisation; after all, the commonest action of hydroquinone is to inhibit oxidations. Further, is it not likely that, where hydroquinone inhibits polymerisation, it does so because it inhibits the formation of those oxidised compounds which so often seem to act as catalysts for the polymerisation of unsaturated compounds, *i.e.*, that even in these cases, its action is essentially anti-oxidative? It may perhaps be very difficult to separate oxidation from polymerisation reactions in these drying oils; but the importance of doing so, if possible, is very great. I am very glad that Mr. Gee is following the course of these reactions in the monomolecular films, where the orientation of the molecules can easily be determined; but I am anxious to see more convincing proof that the changes in area are really due to polymerisation instead of to oxidation, for oxidation would appear the simpler explanation of area increases, from what is known already about the behaviour of surface films of long chain fatty compounds.

**Dr. N. K. Adam** (*after further communication*): I am much obliged to Mr. Gee for clarifying the evidence, and also for being good enough to show me some of the surface pressure-area curves on the material in the various stages from unoxidised to oxidised and polymerised. These curves afford strong additional evidence for his theory; the "fully polymerised" curve is that of a coherent film at low pressures, while that of the "stable isomer" of the unpolymerised oxidised film is apparently gaseous at low pressures; at higher pressures the curves cross and it is clear that there would be an increase in area, measured at medium and high compressions, accompanying the polymerisation. May I say that I now think he has made out an excellent case for his scheme of reactions.

**Dr. J. H. de Boer** (*London*) said: Perhaps it may be possible that the unstable peroxide  $\text{XO}_2^*$  does not change into the stable one when it is absolutely dry. This leads to the following suggestion. Should it be possible to oxidise the molecules  $\text{X}$  to  $\text{XO}_2^*$  when spread on a clean metal surface (*e.g.* obtained by sublimation *in vacuo*) in a dry atmosphere, then afterwards this surface might be rinsed with dilute sulphuric acid to spread the  $\text{XO}_2^*$  on this liquid and perhaps so the polymerisation of  $\text{XO}_2^*$  could be studied apart.

**Dr. E. Bergmann** (*Rehoboth*) said: The suggested reaction scheme reminds one very much of the mechanism proposed by Bodenstein for the oxidation of acetaldehyde, acetylene and similar compounds. An unstable peroxide  $\text{XO}_2^*$  is formed, *e.g.*,  $\text{CH}_3 \cdot \text{CH}=\text{O}$ , which by reaction with a

second molecule  $\text{X}$  (*i.e.*, acetaldehyde) gives a stable peroxide  $\text{XO}_2$  (*i.e.*, peracetic acid) and an "active" molecule  $\text{X}^*$  which has been designed a

In our case, the active molecule  $\text{X}^*$  stabilises by polymerisation. The parallelism is rather striking. It may be added that even in the most common case of the autoxidation of benzaldehyde there are two known substances  $\text{XO}_2$ ; in addition to the "normal" product, perbenzoic acid, a preliminary compound, which is the real carrier of the autoxidation process. The latter accounts for the transmission of half of the oxygen atoms taken up on to other aldehyde molecules—and may stabilise into perbenzoic acid by a side-reaction of the autoxidation process.

**Dr. R. Spence** (*Leeds*) said: The results which we have obtained at Leeds<sup>7</sup> appear to be in agreement with the theory propounded by Norrish and Carruthers. In addition to the carboxylic acid catalysts studied by them, we have found that rapid polymerisation occurs when the walls of the reaction bulb are moistened with sulphuric acid. An attempt was also made to determine the nature of the equilibrium between solid and gas. Some of the polymer prepared at room temperature was heated up in the presence of the monomeric gas and a stationary condition was attained at 80°, when polymerisation and depolymerisation became equal. The nature of the gaseous product of depolymerisation has not yet been studied, but it is interesting to note that Auerbach<sup>8</sup> has found the vapours of certain polyoxymethylenes to consist of molecules of the type  $(CH_2O)_n$ , where  $n$  may be as large as 8. However, when the room temperature polymeride was maintained at 80° for 17 hours, the rate of depolymerisation became extremely small. This is probably due to condensation of the end groups and the formation of longer chains or to the closer packing of existing chains, perhaps by cross linkages of the peroxide type. The chain mechanism of polymerisation advocated by Norrish and Carruthers is supported by other observations. Chlorine and formaldehyde react to give HCl and CO. If the proportion of formaldehyde is greatly increased, rapid polymerisation occurs.<sup>9</sup> Reference may also be made in this connection to Lenher's observation<sup>10</sup> that the presence of one per cent. of oxygen in ethylene at 500° greatly accelerates the rate of polymerisation, although in this case more than one molecule of polymeride results from a single reaction chain.

**Dr. G. Gee** (*Cambridge*) said, *in reply to Dr. de Boer*: The technique of spreading monolayers on metals has scarcely been sufficiently developed for this method of obtaining a pure peroxide film to be immediately practicable. It is, however, hoped at some future date to investigate reactions in monolayers on metallic substrates.

*In reply to a question asked by Dr. Kienle*: The experiments have been carried out in the main on  $N/10$  or  $N/100$  acid; water is to be avoided on account of its variable  $p_H$ , while the use of alkali introduces difficulties in avoiding contamination, and might lead to hydrolysis of the glyceride. The possibility of using the method for the evaluation of antioxidants is very attractive, and experiments on these lines have already been carried out: this work is now being extended and it is hoped to publish the results shortly.

**Dr. R. C. W. Norrish** (*Cambridge*) said: *In reply to Professor Mark*, I must state that we have not yet investigated the absolute values of the steric factors and the activation energy of the process. The matter is complicated by the fact that the reaction occurs at the cold surface, so that it is difficult to assess the number of collisions made by the gaseous monomeric form with the reactive points of the growing chain. Experiments over a wider range of temperature are, however, planned, and it is hoped that it will prove possible to obtain at least a partial insight into these matters.

We have not yet studied the effect of gaseous alkaline substances on the polymerisation of formaldehyde.

*In reply to Dr. Spence*, I should like to say that his observations of the depolymerisation equilibrium of the freshly formed solid polymer with the monomeric formaldehyde at 70° C. is especially interesting, and is in full accord with the curves shown in Fig. 8 on our paper. The fact that on keeping the polymer overnight no such equilibrium was observed suggests that there is a change in the structure of the polymer on standing, and it

<sup>7</sup> Spence, *J. Chem. Soc.*, 1933, 1103; Spence and Wild, *ibid.*, 1935, 338, 506.

<sup>8</sup> Auerbach, *Arch. Kais. Gesundheit.*, 1907, **22**, 584; 1907, **27**, 183; 1914, **47**, 116.

<sup>10</sup> Lenher, *ibid.*, 1931, **53**, 3756.

will be interesting to compare the chemical properties of the two forms. He refers to the polymerisation induced by the reaction between chlorine and formaldehyde. This could be effected by the hydrogen chlorided produced which by addition to the monomeric formaldehyde would produce a hydroxyl group from which the Staudinger chains could grow.

We tried the effect of HCl on the polymerisation of formaldehyde, but though it was positive, it was small and no greater than that of water vapour. (See curve in Fig. 11 of our paper.) This is readily understood when it is seen that according to our mechanism, though both of these bodies can give rise to chains, neither can cause branching, and it is this latter factor which accounts for the enormously greater effects of formic and acetic acids.

## MAGNETISM AND POLYMERISATION.

BY JOHN FARQUHARSON.

*Received 4th July, 1935.*

### I. Introduction.

Although magnetic research has been used to show that a paramagnetic molecule may polymerise to form a diamagnetic complex, and measurements have been made on such systems in order to determine whether the molecule is single or more complex, it is remarkable that very little use has been made of the change in magnetic susceptibility when diamagnetic molecules polymerise. Recently Cabrera and Fahlenbrach<sup>1</sup> have shown that there is a depolymerisation of water resulting from the solution of salts, also it has been recognised that the change in the susceptibility of water with temperature results from a depolymerisation effect. It is the purpose of this paper to draw attention to the fact that magnetic measurements in purely diamagnetic systems can be used to follow the course of a polymerisation, and, in favourable circumstances, may be used to calculate the degree of polymerisation, i.e. the molecular weight of the complex.

### II. The Additivity of Magnetic Susceptibility.

#### (1) Pascal's Work.

The exhaustive researches of Pascal<sup>2</sup> into the susceptibility of both inorganic and organic compounds have shown that magnetic susceptibility may be treated as an additive property. Pascal was able to deduce magnetic constants for atoms in combination in different molecules, but in order to predict correctly the susceptibility of molecules it was necessary to introduce certain constitutive values depending on the types of chemical linkages within the molecule.

<sup>1</sup> Cabrera and Fahlenbrach, *Z. Physik*, 1933, **85**, 568.

<sup>2</sup> For references, recalculation and discussion see Stoner, "Magnetism and Matter," pp. 469-474.

Pascal gave the expression for molecular susceptibility

$$\chi_M = \sum nA\chi_A + \lambda$$

where  $nA$  is the number of atoms in the molecule of susceptibility  $\chi_A$  and  $\lambda$  is the constitutive constant depending on the chemical links.

## (2) The Change in Magnetic Susceptibility Resulting from a Chemical Reaction.

The author<sup>3</sup> has shown on purely experimental evidence that in simple addition reactions there is a change in magnetic susceptibility

TABLE I.—CHANGE OF MAGNETIC SUSCEPTIBILITY IN ADDITION REACTIONS.

Reaction.	Change in Molecular Diamagnetism.
$\text{NH}_3 + \text{HCl} \rightarrow \text{NH}_4\text{Cl}$ . . . .	Fall 4.39
$\text{NH}_3 + \text{HBr} \rightarrow \text{NH}_4\text{Br}$ . . . .	Fall 1.79
$\text{NH}_3 + \text{HI} \rightarrow \text{NH}_4\text{I}$ . . . .	Rise 3.14
$\text{H}_2\text{O} + \text{SO}_2 \rightarrow \text{H}_2\text{SO}_4$ . . . .	Fall 2.50
$\text{H}_2\text{SO}_4 + \text{K}_2\text{SO}_4 \rightarrow 2\text{KHSO}_4$ . . . .	Fall 4.50
$\text{CH}_3\text{NH}_2 + \text{HCl} \rightarrow \text{CH}_3 \cdot \text{NH}_2 \cdot \text{HCl}$	Fall 4.47

consequent on the formation of a new chemical link, and that this change is usually in the direction of a fall in molecular susceptibility as shown in Table I.

That this change is a fall in diamagnetism is not necessarily correct because it will depend largely on the type of chemical link.

If, in an organic reaction, it involves the change from a  $-\text{C}=\text{C}-$  double bond to two single bonds, then according to Pascal's values there will be a rise in diamagnetic susceptibility of  $5.5 \times 10^{-6}$ .

## III. Magnetic Changes during Polymerisation.

When polymerisation takes place between two molecules, B, to form a new molecule, the magnetic susceptibility of the new molecule will be given by an expression of the same type as that given by Pascal for the formation of a molecule from atoms namely,

$$\chi_M = 2\chi_B + \lambda$$

where  $\chi_B$  is the molecular susceptibility of the molecule B, and  $\lambda$  is the constitutive factor arising from the new chemical bond. If  $n$  molecules B react to form a polymer  $nB$ , the general expression for the molecular susceptibility of the polymer will be

$$\chi_M = n\chi_B + (n-1)\lambda$$

and the curve given by plotting  $\chi_M$  against  $n$  will be a straight line. The mass susceptibility of the complex will be given by the expression

$$\chi = \frac{n\chi_B + (n-1)\lambda}{nM_B},$$

where  $M_B$  is the molecular weight of the simple molecule B. In this expression  $\chi_B$ ,  $M_B$  and  $\lambda$  are constants and the curve for the change in mass susceptibility with the number of simple molecules in the complex will be a hyperbola.  $\lambda$  is given by Pascal's results so that by measuring  $\chi$ , the mass susceptibility, it should be possible to calculate  $n$ . If  $n$  is small then it should be given with a fair degree of accuracy, but if it

<sup>3</sup> Farquharson, *Phil. Mag.*, 1932, 14, 1003.

is large it will be rather uncertain. It will always be possible to give a lower limit for  $n$  and thus for the molecular weight. Also, it should be possible to follow the course of a polymerisation process.

#### IV. Following the Course of a Polymerisation.

If a polymerisation proceeds straightforwardly then the susceptibility plotted against time should give a hyperbola such as that for 2, 3-dimethylbutadiene in the Figure.

In the majority of the methods used for the measurement of magnetic susceptibility, it is the volume susceptibility,  $K$ , which is measured and the mass susceptibility then found by the relation  $\chi = K/\rho$  where  $\rho$  is the density. If the mass susceptibility is increasing as the polymerisation proceeds, which is usual as the polymerisation often involves the disappearance of one or more double bonds, the increase in volume susceptibility will be even more marked, because in these polymerisation processes the density also increases greatly.

It is very easy to follow the change in susceptibility as the polymerisation proceeds by means of the Gouy method where the susceptibility is found from the force on a cylindrically shaped specimen suspended with one end between the pole pieces of the electro magnet where the field is uniform, and the other end where the field is negligible. If  $K_1$  and  $K_2$  are the volume susceptibilities of the specimen and the medium in which it is suspended,  $A$  the cross section of the specimen, and  $H$  the field, then the force on the specimen is given by

$$F = \frac{1}{2} (K_1 - K_2) AH^2$$

The force is easily measured by suspending the specimen from one arm of a sensitive weighing balance and is given by the difference in weight with and without the field.  $F$  then gives a direct measure of the volume susceptibility.

In actual practice where a liquid is being polymerised by heat, the specimen is placed in a uniform glass tube of cross section about 0.5 sq. cm., which is then drawn off into the form of a hook to allow of easy suspension. The tube may be previously standardised as to cross section and susceptibility. It is important that the column of liquid is sufficiently long to ensure that after polymerisation and resultant shrinkage the upper end of the column is still in a position of negligible field.

By using a sealed tube it is also possible to obtain an estimate of the density. The weight remains constant and by cooling the specimen to some standard temperature each time a measurement is made, and measuring the length of the column of liquid, it is possible to calculate the density. Should the final product of polymerisation be a solid, care must be taken to see that shrinkage does not leave a space between the solid and the walls of the containing tube and so alter the cross section. As a rule it is not necessary to measure the density during the polymerisation as it is the mass susceptibilities of only the initial and final states which are required.

#### V. The Change in Susceptibility of 2, 3-dimethylbutadiene as it Polymerises at 146° C.

The dimethylbutadiene was prepared from freshly distilled pinacone by heating with potassium pyrosulphate. The fraction containing the dimethylbutadiene was dried over calcium chloride, distilled, and finally distilled over sodium.

The measurements were made by the Gouy method just described. The polymerisation was done at  $146^{\circ}\text{C}$ . Before each measurement the tube was removed from the heating furnace and cooled to room temperature. The alternate heating and measuring were continued for some days

FIG. 1.

until the polymerisation was judged to be complete, the dimethylbutadiene having become quite viscous. The results are shown in the first and second columns of Table II, and in Fig. 1. The results are given as the force in milligrams

on the specimen in the magnetic field.

For comparison with the magnetic result, some results by Lebedeff<sup>4</sup> are given in columns three and four of the Table and also in the Figure. Lebedeff estimated the amount of unchanged material after different times of heating at  $150^{\circ}\text{C}$ . It will be noticed that there is a change of about 2 per cent. in the volume susceptibility and that the susceptibility increases steadily with the time of polymerisation showing that the polymerisation proceeds steadily.

The density was not measured as the polymerisation proceeded, so the curve for the mass susceptibility cannot be given, but the mass susceptibilities of the initial and final products are,

Initial

$$\chi = -0.670 \cdot 10^{-6}$$

$$\rho = 0.730$$

Final

$$\chi = -0.7305 \cdot 10^{-6}$$

$$\rho = 0.823$$

## VI. The Polymerisation of Cyclopentadiene at Room Temperature.

Cyclopentadiene affords an example of a susceptibility-polymerisation curve which falls with increasing polymerisation. The substance was

<sup>4</sup> Lebedeff, *J. Russ. Phys. Chem. Soc.*, 1913, **45**, 1313.

allowed to polymerise at room temperature, and the mass susceptibility was measured at intervals on a Curie-Cheneveau magnetic balance. The author is indebted to Dr. Wasserman of this department for a sample of freshly distilled cyclopentadiene. The results are given in Table III.

According to Barratt and Burrage<sup>5</sup> cyclopentadiene polymerises fairly rapidly at room temperature to dicyclopentadiene and a small proportion of higher polymerides, and any further polymerisation takes place slowly. The magnetic results are in agreement with this view, but the value  $-0.680 \times 10^{-6}$  cannot be taken as that of the dimer because the sample was still liquid and contained unchanged cyclopentadiene.

## VII. Further Examples of Change of Susceptibility with Polymerisation.

### (1) Cyanogen Chloride.

Cyanogen chloride was prepared by the method of Price and Green<sup>6</sup> by the action of chlorine on HCN. It was purified by distillation over sodium bicarbonate and zinc oxide. The substance was redistilled immediately before measurements were made. Cyanogen chloride polymerises readily in the presence of a little HCl to give the white solid polymer cyanuric chloride. The results are as on table opposite. The change in susceptibility when three molecules of cyanogen chloride polymerise to form cyanuric chloride is  $(3 \times 32.4 - 81)10^{-6} = 16.1 \times 10^{-6}$  or 16.5 per cent.

### (2) Nitrosobenzene.

Nitrosobenzene is a white solid at room temperature. When molten or in solution it is green and thus falls into line with other nitroso compounds. The colour change has been taken as an indication that nitrosobenzene is polymerised in the solid state. Cryoscopic data support this view.<sup>7</sup> In acetic acid the molecular weight is 112 (theory 107) indicating polymerisation, and in benzene 101.6 — 106.

Magnetic results for nitrosobenzene are given in Table IV.

No really reliable figure can be given for the susceptibility of nitrosobenzene in benzene because of its slight solubility, but all the measurements made showed it to be less diamagnetic than when molten. The measurement on the liquid was made

TABLE IV.—SUSCEPTIBILITY OF NITROSOBENZENE UNDER DIFFERING CONDITIONS.

State of Compound.	$-\chi \times 10^6$ .
(1) Solid . . .	0.563

(3) Molten . . .	0.450
(4) In benzene . . .	less diamagnetic than when molten

<sup>5</sup> Barratt and Burrage, *J. Phys. Chem.*, 1933, **37**, 1029.

<sup>6</sup> Price and Green, *J. Soc. Chem. Ind.*, 1920, p. 30.

<sup>7</sup> Bamberger and Renaud, *Ber.*, 1897, **30**, 2278; Bamberger and Rising, *Ber.*, 1907, **34**, 3878.

at 72° C., which is only 2° above its melting-point. Higher temperatures for the time necessary to make a measurement gave rise to decomposition.

The magnetic results support the view that the solid nitrosobenzene is polymerised. It would appear that there is still a quantity of polymer in acetic acid and also a small amount in molten nitrosobenzene just above the melting-point.

### Discussion.

#### Dimethylbutadiene.

According to Stoner's recalculations of Pascal's values for magnetic constitutive effects the values for  $\lambda$  for a double bond and a conjugated double bond respectively are

Whitby and Crozier<sup>8</sup> have shown that dimethylbutadiene which has been polymerised for fifteen days at 150° contains 63 per cent. of a dimer and 37 per cent. of higher polymers. The higher polymers still contain one double bond per diene group as does the dimer because it is a ring compound, so that one double bond disappears for each addition of a dimethylbutadiene molecule. In this case the bond change  $\lambda$  will be 5.1 and the application of the formula

$$\chi = \frac{n\chi_B + (n-1)\lambda}{nM_B}$$

gives a value for  $n = 36.4$  i.e., the mean molecular weight is 2985. On the other hand, if the bond change is simply looked upon as the disappearance of a double bond,  $\lambda = 5.5$ , and  $n = 10$ . The mean molecular weight is 820.

If the results of Lebedeff and Whitby are combined then the mixture of polymers measured magnetically should contain approximately

$$\left. \begin{array}{l} 12.1 \text{ per cent. of monomer} \\ 55.4 \text{ per cent. of dimer} \\ 32.5 \text{ per cent. higher polymers} \end{array} \right\} \text{mean molecular weight 750,}$$

but the percentage of higher polymers may be slightly higher and that of dimer lower, as after 12.5 hours heating at 145° C. the ratio of higher polymers to dimeric oil is higher. It appears from this that the bond change in a polymerisation process of this type is 5.5 and not 5.1. The agreement is very good but the result may not be reliable as Pascal's values cannot be regarded as precise, but are only average values, and for this type of work very reliable and accurate values are required for the bond changes involved. This result for dimethylbutadiene can only be regarded as a preliminary one. A more accurate examination is being carried out on isoprene and its polymerisation products, for here, at least, some of the simpler polymerisation products are known in the form of the terpenes.

#### Cyclopentadiene.

According to the accepted view of the polymeric cyclopentadienes the mass susceptibility of cyclopentadiene should rise as it polymerises,

<sup>8</sup> Whitby and Crozier, *Canadian J. Research*, 1932, 6, 203.

as polymerisation results in the disappearance of two double bonds. Instead of a rise there is a fall which is difficult to explain unless there is a large fall in diamagnetism due to the bridged ring of the terminal six membered ring of the polymeric cyclopentadiene.

### Cyanogen Chloride.

The value of 32.4 for ClCN is slightly higher than that given by Pascal's values, 30.8. This is only to be expected because although Pascal's atomic values give good results, it is the values of certain groupings which are more likely to give additive results than atomic values. However, it will be seen that the large change in diamagnetism when cyanogen chloride polymerises to cyanuric chloride can be explained readily by the use of Pascal's values. The commonly accepted view of the polymerisation is

According to Pascal, the bond constitutive effects are

so that the disappearance of 3(C≡N) bonds should raise the susceptibility by 2.4 and the appearance of 3(C=N) bonds should lower it by 24.6, a net change of 22.2 whereas the change found experimentally is 16.1.

### Nitrosobenzene.

The susceptibility of the nitroso compounds is slightly abnormal and will be treated more fully in another publication, but if the structure is formulated in the old way, then

The double bonds disappear from between the oxygen and the nitrogen which would make the polymer more diamagnetic than the monomer as is found experimentally.

### Summary.

Polymerisation gives rise to a change in diamagnetic susceptibility which can be followed quite easily. As polymerisation proceeds, the mass susceptibility follows a curve which, in the normal case, is a hyperbola. If the degree of polymerisation is not too great then it can be calculated by using Pascal's atomic values or constitutive constants. Pascal's values can also be used to explain the changes in susceptibility when the polymers can be separated.

The author expresses his thanks to Professor F. G. Donnan for his continued interest and advice, to the Commissioners for the Exhibition of 1851 for a Senior Studentship with which this work was begun, and to Imperial Chemical Industries for a Grant.

### GENERAL DISCUSSION.

Dr. R. J. W. Le Fèvre (*London*) said: Abnormalities in the case of nitrosobenzene are not unexpected, since a completely satisfactory formula—upon the basis of which such an additive property as magnetic susceptibility could be calculated—is lacking for this substance. Experimental evidence showing that monomeric nitrosobenzene cannot be regarded as containing a tercovalent N atom (as required by the older formula) has been cited previously (Le Fèvre),<sup>9</sup> whilst from a consideration of the variable and at first sight contradictory electropolar properties of the nitroso group in aromatic compounds (polarisation<sup>10</sup> and polarisability<sup>11</sup> effects), the conclusion was reached<sup>12</sup> that Ar-nitroso compounds must be formulated uniquely. To this end a suggestion was advanced that these phenomena would be understandable if the NO radical were to exhibit degeneracy to a certain degree between the unperturbed forms  $-\text{N}^{\cdot}(\text{O})$  and  $-\text{N}^{\cdot+}-\text{O}^{\cdot-}$ . Expressed in a current nomenclature,<sup>13</sup> it can be said that an Ar-NO group is to be classified as having superposed polarisations of  $-I$  and  $-M$  types along with polarisability possibilities denoted by  $\pm E$ .

## PART II.—SPECIAL.

### RECENT PROGRESS IN THERMAL POLYMERISATION AND CONDENSATION OF GASEOUS HYDROCARBONS.

BY A. E. DUNSTAN.

*Received 3rd September, 1935.*

In a recent communication<sup>1</sup> "Thermal Treatment of Gaseous Hydrocarbons—(1) Laboratory Scale Operation," attention was drawn to the possibility of utilising gaseous hydrocarbons, such as natural gases, and gases from oil-cracking plants, as sources of motor fuel of high anti-knock value.

From the industrial viewpoint, the production of liquid hydrocarbons from gaseous paraffins and olefines is of great importance owing to the vast quantities of these hydrocarbons available for development.

The quantities of gaseous olefines available are more difficult to estimate because of the considerable variation in the gases produced in cracking operations. A figure of 300,000 million cu. ft. may be taken as the volume of cracker gas produced in a year, and of this it is estimated that the quantities of gaseous olefine hydrocarbons available from this source, expressed in millions of cu. ft. are: ethylene, 16,500; propylene, 2000; butylenes, 11,000.

#### Polymerisation of Olefines.

Historical references are given in two papers by Dunstan, Hague, and Wheeler.<sup>2</sup> Further, in these two papers is developed the general theory of the polymerisation of the simpler olefines as set out in the following paragraphs.

With the olefines, ethylene, propylene, and the two unbranched butylenes, the principal primary reactions, common to all, involve the formation of either the two-carbon or the four-carbon (or both) atom members of the olefine series. These reactions may be represented by: (i)  $2C_2H_4 = C_4H_8$ ; (ii)  $2C_3H_6 = C_2H_4 + C_4H_8$ ; (iii)  $C_4H_8 = 2C_2H_4$ . Whilst the exact mechanism of reactions (ii) and (iii) is obscure, it has been shown that reaction (i) is a true polymerisation.

If conditions are at all drastic, decomposition is not limited to the the primary changes, and secondary reactions occur, such as the

<sup>1</sup>A. E. Dunstan, E. N. Hague, and R. V. Wheeler, *Ind. Eng. Chem.*, 1934, **26**, 307.

<sup>2</sup>*J.S.C.I.*, 1931, **50**, 313, and *J.S.C.I.*, 1932, **51**, 131.

decomposition of butylene to give butadiene and hydrogen in one case, and propylene and methane in the other:

An important secondary change with propylene is the formation of methane and ethylene, probably by hydrogenation of the radicals formed by scission of the carbon chain at the single linking, as shown by:

Of the two butylenes, it was found that  $\Delta^8$ -butylene was more stable than  $\Delta^2$ -butylene. Three changes appear to be operative to approximately the same extent at  $600^\circ$ : (i) Depolymerisation to ethylene, accompanied by the secondary hydrogenation of the ethylene to ethane. (ii) Scission of the carbon chain at the end single linking, with the formation of radicals which by hydrogenation give rise to propylene and methane. (iii) A dehydrogenation of butylene to form butadiene.

It has been shown that, following on the production of butylene from ethylene, secondary decomposition to give butadiene occurs. Furthermore, ethylene and butadiene combine in equimolecular proportion, at comparatively low temperatures, to produce cyclohexene. Thus it would appear that, following on the primary modes of decomposition, there is the production of hydroaromatic and then aromatic hydrocarbons. With both paraffins and olefines, ethylene would appear to be the starting-point for these changes. The experiments of Dunstan, Hague, and Wheeler show, then, that ethylene readily polymerises to butylene, that butylene by dehydrogenation produces butadiene, that butadiene and ethylene unite in equimolecular proportions to give cyclohexene, and that cyclohexene finally produces benzene.

The exact mechanism of the addition of ethylene to butadiene is not clear. There are indications that an open-chain hexadiene and then a cyclohexadiene may be intermediate steps in this change, but no satisfactory proof of this can be adduced as yet.

By analogy with the formation of diphenyl from benzene, it is

TABLE I—PYROLYSIS OF THE OLEFINES FOR THE PRODUCTION OF AROMATIC HYDROCARBONS AT ATMOSPHERIC PRESSURE

Gas.	Temp	Conversion into Liquids	Conversion into Light Spirit.
		Per Cent.	Per Cent.
Ethylene	$800^\circ$	36.1	17.7
Propylene	$750^\circ$	35.6	20.4
	$800^\circ$	40.6	19.0
$\Delta^2$ -Butylene	$700^\circ$	35.8	23.6
	$750^\circ$	39.6	22.45
$\Delta^8$ -Butylene	$700^\circ$	37.0	25.8
	$750^\circ$	39.6	23.2

reasonable to suppose that butadiene can condense with benzene, hydrogen being eliminated, to form naphthalene, and that anthracene and phenanthrene can be formed from naphthalene in a similar manner. It is interesting to note that considerable quantities of styrene were found in the liquids obtained when operating on a semi-large scale. The

most obvious explanation of the presence of styrene is by condensation of ethylene and benzene, with the elimination of hydrogen.

The olefines, ethylene, propylene, and the branched butylenes, have

been considered individually in a pure state. As with the paraffin hydrocarbons, it was found that, following on the primary reactions brought about by heat-treatment, secondary reactions occur which lead to the production of aromatic hydrocarbons. This stage in the pyrolysis of the olefines closely resembles that observed with the paraffin hydrocarbons. Some of the figures obtained are given in Table I.

At lower temperatures, however, true polymerisation without these secondary changes occurs. Thus it is found that at all pressures from 200 to 2000 lb. per sq. in. over the temperature range 350°-600° liquid hydrocarbons can be produced from ethylene. Neither 200 nor 2000 lb. per sq. in. is a limiting pressure for this effect, but this range has proved convenient. As the pressure is increased, the temperature necessary to effect polymerisation is reduced. Under suitable conditions it is possible to operate without the production of more than traces of saturated gases from the olefine hydrocarbons, but always, if conditions are too drastic, deposition of carbon accompanied by the production of hydrogen and saturated gaseous hydrocarbons occurs.

The liquid hydrocarbons from continuous operation possessed a light straw colour and were quite transparent. The boiling range of these liquids varied with the conditions of temperature and pressure of their production, but the usual product had a specific gravity of 0.75 to 0.77 at 15° C., and 80 to 86 per cent. distilled below 200° C. The liquid has been fractionated through an efficient fractionating column, and "steps" occur at 37° to 39°, 64° to 66°, 94° to 98°, 100° and 120° C. These steps, together with the evidence supplied by gas analysis, indicate the presence of olefines or paraffins, or both, containing from 3 to 8 carbon atoms to the molecule. Thus, from gas analyses, propylene, the butylenes and the amylenes are present. Furthermore, the percentage unsaturation of the liquid fractions has been estimated, and it has been found that this decreased with rise in temperature from 75 to 80 per cent. in the region of 39° C., to 50 per cent. in the 120° C. range. Thus the polymerides are largely olefinic, with an increasing proportion of paraffins as the boiling-point increases. All fractions were stable when exposed to sunlight, and gave no reaction with maleic anhydride. These facts are taken as evidence that hydrocarbons containing conjugated double bonds in the molecule were absent. There are, however, indications of the presence of naphthenes.

A brief account follows of work only published very recently or described in current meetings, particularly of the American Chemical Society in New York this spring.<sup>3</sup>

### **Cracking and Polymerisation of Low Molecular Weight Hydrocarbons.**

Considerable interest has been shown lately in the polymerisation of gaseous olefines for the production of anti-knock fuels. The writers have already presented some results of a general nature on the subject.<sup>4</sup>

#### **Polymerisation of Olefines.**

At low temperatures, in the absence of catalysts, the olefines require a long time of heating to produce good yields of liquid products. At higher

<sup>3</sup> By P. K. Frolich and P. J. Wiezevich, presented before the Petroleum Division, American Chemical Society, New York Meeting, April 22-23, 1935.

<sup>4</sup> Frolich and Wiezevich, *Ind. Eng. Chem.*, 1932, **24**, 13

temperatures the rate of polymerisation is much greater, but a different type of product is obtained.

### Use of Catalysts with Olefines.

A large number of catalysts and contact materials have been reported for the polymerisation of olefines. Silicon, copper, and noble metals, boron fluoride, zinc chloride, boron fluoride with hydrogen halide, aluminum chloride with zinc and others have been shown to have high activity. By means of boron fluoride accompanied with finely divided nickel the polymerisation of ethylene may be controlled to give high yields of butylene.

Silica gel was found to catalyse the formation of aromatics from propylene at 650° C. Clay at 170° to 370° C. at 600 to 1500 lbs. pressure has also been found effective in polymerising gaseous olefines. Gayer prepared a synthetic alumina-silica catalyst which is more active in polymerising propylene at atmospheric pressure than Floridin clay, at 350° a 30 per cent. yield per pass of low boiling liquid products was obtained having a high octane number (87 after steam distillation) and boiling mostly in the hexane range.

Phosphoric acid and its salts have also been found effective in polymerising gaseous olefines. Ipatieff has employed orthophosphoric or orthophosphoric acids for polymerising cracked gases.

Other catalysts which have been employed for this purpose are basic zinc chromite, metals of the 8th series, ammonium molybdate, magnesium oxide and bauxite.

## Polymerisation of Gaseous Olefines with Phosphoric Acid.

### Part I. Catalytic Polymerisation of Propylene by means of Phosphoric Acid.<sup>5</sup>

The polymerisation of olefines, both catalytic and non-catalytic, has received little study from the point of view of the chemical mechanism of the process.

Our explanation of the catalytic action of phosphoric acid is based on its ability to form esters with olefines. These esters, in turn, decompose to liberate activated olefine molecules which combine to form polymers.

Experiments have shown that olefines react with phosphoric acid at relatively low temperatures (200° C. for ethylene, 125° C. for propylene) to form esters of phosphoric acid.

At the temperatures employed in actual polymerisation the life of these esters is probably very short. The activated olefine molecules liberated *in statu nascendi* by the decomposition of these esters unite with each other to form polymers. Evidently, according to this hypothesis, a single molecule of phosphoric acid can bring about the polymerisation of many molecules of olefine since the acid is regenerated after each cycle. In one experiment on the polymerisation of propylene by liquid phosphoric acid, the quantity of polymer obtained corresponded to the polymerisation of 110 molecules of propylene by a single molecule of phosphoric acid, and at the end of the experiment the acid was as active as it was at the beginning.

The esters may eliminate the elements of phosphoric acid in different ways, thus giving rise to isomeric polymers. Thus the first formed hexylene may react with phosphoric acid to form hexyl phosphoric acid which in turn may react with propyl phosphoric acid to produce nonylene. In the same way nonyl phosphoric acid may react with propyl phosphoric acid to form dodecylene, or two molecules of hexyl phosphoric acid might produce dodecylene.

<sup>5</sup> By V. N. Ipatieff, presented before the Petroleum Division, American Chemical Society, New York Meeting, April 22-23, 1935.

The polymerisation of propylene proceeds at high velocity at 200° C. under a pressure of 7 to 15 atmospheres. In fact it takes place readily at 135° C. at atmospheric pressure. The liquid polymer obtained by the polymerisation of propylene consists almost entirely of mono-olefins,  $C_nH_{2n}$ . The evidence for this statement as to the chemical nature of the polymer is four-fold: (1) solubility in 96 per cent. sulphuric acid at 0°; (2) behaviour on catalytic hydrogenation; (3) bromine number; and (4) carbon-hydrogen ratio. For example, the propylene polymer was practically 100 per cent. soluble in 96 per cent. sulphuric acid at 0° C. Catalytic Hydrogenation of the polymer at 220° and an initial hydrogen pressure of 96 atmospheres produced only paraffinic hydrocarbons which indicated the absence of naphthenes and aromatics in the original polymer. The bromine number of the polymer agreed with that calculated for mono-olefins, and the carbon-hydrogen ratio corresponded to  $C_nH_{2n}$ .

As mentioned above, the propylene polymer produced at the relatively low pressures of 1 to 15 atmospheres consists of mono-olefins, but under more severe polymerising conditions (higher pressures, temperatures and contact times), aromatic hydrocarbons are also formed. This is especially true in the catalytic polymerisation of ethylene.

In the polymerisation of a mixture of olefins, such as propylene and butylene, there is obtained not only the polymers of each of these hydrocarbons, but also mixed polymers due to combination of the two hydrocarbons. The evidence for this conclusion is Podbielniak distillation data of the liquid products obtained from individual olefins and from mixtures. The formation of a mixed polymer can be represented by the following equation.

### Polymerisation of Propylene at Superatmospheric Pressure with "Solid Phosphoric Acid."

Many experiments were made on the polymerisation of propylene and of other olefins in the presence of so-called "solid phosphoric acid" catalysts. These contact masses were prepared by mixing phosphoric acid with various carriers. These solid catalysts, being non-corrosive in spite of their high acid content, could be used in ordinary steel apparatus. The catalytic activity depended to a considerable extent upon the method of preparation and upon the character of the solid absorbent.

Pursuing the same line of attack Ipatieff and Corson dealt with the butylenes.

### Polymerisation of Gaseous Olefins with Phosphoric Acid. Part II. Catalytic Polymerisation of the Butylenes by means of Phosphoric Acid.<sup>6</sup>

The isomeric butylenes are polymerised by phosphoric acid at relatively low temperatures and atmospheric pressure to liquid polymers. These polymers are mono-olefins. Iso-butylene polymerises the most readily, and  $\alpha$ -butylene the least. The presence of iso-butylene accelerates the polymerisation of the  $n$ -butylenes (but it is certain that *iso*-butene may be better handled as a source of *iso*-octane).

Special attention should be drawn in this connection to the reactions of isobutene. This hydrocarbon exists in the  $C_4$  fraction of cracked gases

<sup>6</sup> By V. N. Ipatieff and B. B. Corson, presented before the Petroleum Division, American Chemical Society, New York Meeting, April 22-23, 1935.

(and especially in high temperature cracking) and may be absorbed and polymerised by means of moderately concentrated sulphuric acid (probably via tertiary butyl alcohol and its degradation) into di-isobutene. This, of course, is readily reduced into iso-octane (the standard hydrocarbons for high anti-knock efficiency).

### The Polymerisation of Propylene.<sup>7</sup>

Gayer's work<sup>8</sup> on the polymerisation of olefines by acid catalysts was repeated with the purpose of ascertaining whether or not the five-, seven-, and eight- carbon olefines are actually formed.

The activity of the Gayer catalyst and the nature of the polymer were confirmed. Olefines not corresponding to multiples of the propylene molecule were clearly indicated in the distillation curves, and their presence definitely proved by the isolation and identification of certain individual hydrocarbons. Trimethylethylene composed the major portion of the pentene fraction, and evidence is presented that the seven- and eight-carbon groups contained 3-methylhexene-1 and 2, 3-dimethylhexene-2, respectively.

Examination of the dipropylene fraction demonstrated that it was composed primarily of two olefines, 2-methylpentene-2 and tetramethylethylene, and a saturated hydrocarbon, 2-methylpentane. Similarly, a mixture of heptanes, apparently 2-methylhexane and 2,3-dimethylpentane, were found in the next fraction. Small amounts of benzene and toluene were also almost certainly present in the mixture.

This remarkable variety of products might appear to be the result of cracking rather than polymerisation; yet further study showed that no gaseous products other than ptenenes were produced in the reaction. These results and the absence of any appreciable amount of product above  $C_{11}$  are in sharp contrast to those obtained under milder conditions with more easily polymerised olefines such as isobutylene. The latter gives an apparently limitless series of hydrocarbons which, however, are multiples only of isobutylene.

### Pyrolysis and Polymerisation of Gaseous Paraffins and Olefines.<sup>9</sup>

The exothermic character of the polymerisation reaction has been observed by many investigators in this field, in fact Waterman and Tulleners state that "ethylene at a temperature above 350° C. and under a pressure of 175 Kg./sq. cm. (ca. 175 atmospheres) decomposes with explosive violence."

### The Productions of Gasoline by Polymerisation of Olefines.<sup>10</sup>

The  $C_4$  fraction from the total gas yield was studied. Its approximate composition is 60 per cent. butene-1, 25 per cent. iso-butene, 13 per cent. 1,3-butadiene, and 2 per cent. a mixture of *n*-butane and isobutane.

From a survey based on the products obtained over the whole temperature range of thermal reactions of gaseous hydrocarbons, ethylene may be regarded as the basic hydrocarbon. The detailed nature of its thermal

<sup>7</sup> Preliminary Paper, by Frank C. Whitmore and Robert F. Marschner, presented before the Petroleum Division, American Chemical Society, New York Meeting, April 22-23, 1935.

<sup>8</sup> *Ind. Eng. Chem.*, 1933, **25**, 1122.

<sup>9</sup> By F. W. Sullivan, Jr., R. F. Ruthruff, and W. E. Kuentzel, presented before the Petroleum Division, American Chemical Society, at New York, April 22, 1935.

<sup>10</sup> By C. R. Wagner, presented before the Petroleum Division, American Chemical Society, New York Meeting, April 22-23, 1935.

reactions gives the key to the decomposition of any hydrocarbon since ethylene is an important product below  $750^{\circ}$  and since above  $750^{\circ}$  the products are essentially those of ethylene at that temperature.

By a consideration of five types of reactions for ethylene—(1) polymerisation, (2) hydrogenation to ethane, (3) scission of one C—H bond, (4) scission of the double bond and (5) dehydrogenation to acetylene—the reaction products may be accounted for. Determined or estimated values for the energy of activation for these reactions show inconsistencies arising chiefly from the assumption that ethylene is stable below  $1000^{\circ}$ .

Polymerisation of ethylene to non-aromatic liquids appears to take place by a combination of ethylene radicals or molecules. Experimental evidence does not support the formation of higher olefines by combination with methylene radicals.

The mechanism for the formation of aromatics from ethylene has not been definitely established. Since dehydrogenation of cyclohexane to give benzene does not occur to any appreciable extent without a catalyst, and since the formation of acetylene takes place largely at temperatures higher than the temperatures for the formation of aromatics, a combination of six methylene radicals with the expulsion of six hydrogens due to localised energy has been suggested as a possible source of aromatics.

### Production of Gasolene by Polymerisation of Olefines.<sup>11</sup>

Gases from low-pressure vapour phase cracking containing 20 to 24 per cent. of ethylene, 13 to 18 per cent. of propylene, and 6 to 10 per cent. of unsaturates in the four-carbon group were polymerised to liquid products by heat and pressure in the absence of catalysts.

On a once-through basis 1.7 gallons of gasolene per 1000 cu. ft. were obtained operating at  $950^{\circ}$  F. and 800 lbs. pressure, the yield was increased to 3.0 gallons by recirculating the gas derived from stabilising the liquid products. The yields were improved in a commercial unit to 3.25 gallons. By processing gas from stabilising vapour phase cracked distillates 9.0 gallons were obtained. By operating at low pressure and  $1200^{\circ}$  to  $1300^{\circ}$  F., the liquid products were mostly aromatic.

### Polymer Gasoline from Cracked Gases.<sup>12</sup>

A commercial polymerisation unit recently put into operation is processing 3,000,000 cu. ft. a day of cracked gas, and producing about 5 gal. of polymer gasoline per 1000 cu. ft. This gasoline has an octane rating of 80–82 "motor method," and its blending value is higher than that of benzene or iso-octane.

The process is that developed by the Universal Oil Products Company, and reported at the recent New York meeting of the American Chemical Society.

The unit is operating under mild conditions of temperature and pressure, using a solid catalyst. The stabiliser gas being processed contains about 29 per cent. of propylene and butylenes.

Cracked gases are made up of paraffin hydrocarbons, and also members of the olefinic series—including ethylene, propylene, and butylenes. These olefines react at relatively low temperatures and pressures in the presence of the solid catalyst to produce polymer gasoline.

<sup>11</sup> By C. R. Wagner, *Ind. and Eng. Chem.*, August, 1935, p. 933.

<sup>12</sup> By V. N. Ipatieff and Gustav Egloff. Proceedings—Fifth Mid-Year Meeting American Petroleum Institute, Section III. Refining. Tulsa, Okla., 14–16th May, 1935.

### Properties of Polymer Gasoline.

The outstanding characteristic of polymer gasoline is its high octane number and blending value.

Polymer gasoline has higher blending value than either benzene or iso-octane, although its straight octane value is lower—81 versus 97 and 100, respectively. Its blending value becomes higher the lower the octane number of the base fuel with which it is blended.

### Reactivation of the Catalyst.

The solid catalyst gradually loses its activity with continued use, but it is readily regenerated with a controlled volume of air which burns off the highly polymerised, or carbonaceous material that deposits upon the catalyst. This reactivation step has been carried out a number of times; each time bringing the catalyst back to its original activity. The 22-day run reported in this paper was made with a catalyst which had been regenerated in the tower used for polymerisation.

### Summary.

Experiments are described concerning the polymerisation of five samples of cracked gases in semi-commercial polymerisation units. The operating conditions of gas rate, temperature and pressure varied from 0.05 cu. ft. to 11.4 cu. ft. per hour per pound of catalyst, 450° to 500° F., and 100 to 175 lbs. per sq. in., gauge, pressure. The yields of liquid polymer ranged from 3.0 gal. to 8.4 gal. per 1000 cu. ft., with olefine polymerisations of 71 to 99 per cent.

### GENERAL DISCUSSION.

Captain W. H. Cadman (*London*) said: Dr. Dunstan has outlined in his paper the main points of the experimental work conducted by the Anglo-Iranian Oil Company, leading to the successful polymerisation and condensation of gaseous hydrocarbons on a semi-commercial scale.

A petroleum cracking plant is an essential part of a modern oil refinery equipment, either as a means of increasing the yield of lighter fractions, such as petrol by cracking the heavier residues, or for reforming oils, which means improving the quality of lighter fractions by raising their anti-knock value. Whatever be the type of cracking plant in use, the production of a large quantity of gas is unavoidable, amounting in most cases to many millions of cubic feet per day. These cracked gases have a high olefine content, sometimes as high as 50 per cent. by volume.

It is with the application of polymerisation to these cracked gases that Dr. Dunstan's paper deals. He frankly admits that the exact mechanism of these operations is not yet clear. The discussion on polymerisation in all its aspects at this meeting has gone a considerable way towards helping us to understand the reactions involved. Some new light has been thrown on the problem, but much still remains hazy or unsolved, and will, I fear, not be completely clear until more work has been done on the kinetics of the polymerisation of these gaseous hydrocarbons.

The *Summary* of the paper might convey the idea that the polymerisation of such gases had only reached the semi-commercial operation stage. This is not so. In the paragraph dealing with "polymer gasoline from cracked gases" Dr. Dunstan mentions a commercial polymerisation unit, and I would like to say something more about this great achievement. In addition to the work carried out in this country, a great deal of pioneer work has been done in America, particularly by Dr. Egloff, Professor Ipatieff, and other chemists of Universal Oil Products Company, leading to the completely successful commercial operation stage. To-day a large-scale polymerisation plant treating 3,000,000 cubic feet of gas per day is in

operation at the Shell Refinery in East Chicago, Illinois. There, the gas from the top of the pressure distillate stabiliser of the cracking point, at a pressure of about 150 lbs. per square inch is preheated to from 400° to 450° F. and then passed through several reaction vessels packed with phosphoric acid as catalyst supported on a suitable solid carrier. Half of these reactors are in use while the other half are being regenerated. The polymer product is a liquid of a light yellow colour. It is easily refined to a water-white motor spirit with an octane number of about 80. Dr. Dunstan has referred to the high quality of the polymer, and has pointed out that it is of greater value as a blending agent than benzene or iso-octane. So successful has this first commercial plant proved to be (yielding some 5 gallons of polymer gasoline per 1,000 cubic feet of cracked gas treated) that several other large-scale plants for the commercial polymerisation of olefines are now in course of construction in U.S.A. refineries.

The indications are that every modern refinery will soon find it desirable to add a standard "Poly" plant to their refinery equipment. Such plants are now on sale, and can be bought "over the counter" as it were, to deal with any number of millions of cubic feet of cracked gas per day, and with the yield and quality of polymer product fully guaranteed by the makers. Commercial gas polymerisation is one of the latest and one of the greatest developments in the oil industry. Its importance will be appreciated from the fact that it has opened up a new and valuable source of motor fuel supply.

I am sure, therefore, that all who are interested in the commercial application of polymerisation will join with me in congratulating the American chemists concerned on the translation of the polymerisation process into successful industrial production, and I would ask our American guests to convey these congratulations to their fellow countrymen on their return.

**Dr. P. Lewis-Dale** (*London*) said: Dr. Dunstan's paper deals with a practical application of polymerisation on a very large scale. It is singularly appropriate that it should be read at a meeting of this Society as Faraday himself in 1825 investigated a liquid obtained in the cracking of oil and found in it benzene and butylene. Armstrong (1884) worked on a similar liquid (from the Pintsch Oil Gas process) and isolated several compounds which polymerise readily. In 1924-25, I called attention to the fact that many substances in the liquid (obtained in the compression of oil gas, polymerised spontaneously or when treated with sulphuric acid and other reagents. When the liquid was distilled in glass, there was sometimes violent action at about 130° C., accompanied by evolution of hydrogen and polymerisation. The results noticed bear striking resemblance to some of the reactions mentioned by Dr. Dunstan. The liquid itself and distillates therefrom have very high anti-knock values, higher than that of benzene, which constitutes about 30 per cent. of the liquid.

**Dr. E. Bergmann** (*Rehoboth*) said: The suggested possibility, that naphthalene in the mixtures obtained is formed by interaction between benzene and butadiene, seems unlikely; the reaction should give phenylbutadiene. The following mechanism is preferred. Benzene reacts with ethylene to give styrene, hydrogen being eliminated. As a matter of fact, Dr. Dunstan has observed "considerable quantities" of styrene in his reaction products. A further molecule of ethylene now combines with the styrene according to the scheme.

subsequently, dehydrogenation occurs. The participation of the "conjugated" aromatic double bond in addition reactions of the above type has been observed in several cases: *e.g.*, in the reaction between styrene and diphenylketene, which, in variance with Staudinger's original view, is not a mutual saturation of the two olefinic double bonds of these molecules; in the reaction between asym. diphenylethylene and maleic anhydride (Wagner-Jauregg); in the formation of the so-called dimeric diphenyl ketone of Langenbeck, which is obviously not a cyclobutanedione-derivative, etc. A fuller report on these questions will be given elsewhere.

The formation of phenanthrene and anthracene from naphthalene may be explained according to the same reaction scheme.

## ON THE FORMATION OF CONDENSATION PRODUCTS FROM SIMPLE HYDROCARBONS.

BY MORRIS W. TRAVERS.

*Received 7th August, 1935.*

The products formed by the thermal condensation of simple hydrocarbons are generally very complex, and a good deal of attention has been directed to the study of condensation processes by two methods. In the first place the methods of organic chemistry have been applied to the analysis of the products, conclusions as to the course of condensation processes being derived from the results; or the changes resulting in thermal treatment have been followed by observing changes of pressure. In the following paper an account is given of some experiments which lead to the conclusion that polymerisation may, in many cases be initiated by simple mechanisms, the nature of which can only be disclosed by detailed investigation. Such an investigation has been attempted in the case of ethylene, and also of propylene. A few experiments have been carried out in the case of acetylene, and the work done is sufficient to show that partial investigation of such a problem is more likely to prove confusing than helpful. I am a little doubtful whether the subject, as I treat it, comes within the scope of the discussion; but to deal with the general problems of polymerisation one must begin at the beginning, which is the study of the simplest hydrocarbons, ethylene and acetylene.

The difficulty in investigating condensation processes in the case of hydrocarbons, in common with the study of thermal changes in organic compounds generally, is partly due to the fact that two or more processes generally take place simultaneously, and only very exact analysis makes it possible to follow any single one of them accurately. Further, most processes seem to be more or less influenced by surface phenomena, which have either a positive or negative effect on the velocity of one of these which occur simultaneously. At the same time, the method of detailed analysis which we have used makes it necessary to confine our attention to a comparatively narrow range of temperatures; for at high temperatures the time during which the material is heated is so short that error due to the fact that the reaction tubes must be heated from air temperature to the reaction temperature becomes significant; and at low temperatures the processes become so slow that an investigation takes more time than can reasonably be devoted to it. Great accuracy

is also impossible when the processes are carried out under very low pressures.

In the whole of this investigation a method, which has been described in detail elsewhere, was used; a definite quantity of the reactant gas, or gases, being heated in a silica glass reaction tube to a definite temperature for a definite time, the contents of the tube being then analysed. The course of a reaction was followed by means of a series of such experiments covering different intervals, which made the method laborious. However, it was possible to trace the changes in concentration of each constituent or product exactly.

As it is impossible to follow the processes by means of formulae, methods of computation, of which the following is an example, were used. To determine the velocity constant in the case of the formation of condensation products, the rate of which is dependent on the square of the ethylene concentration, the amount of condensation product ( $R$ ) produced during successive periods was divided by the product of the mean of the squares of the ethylene concentration at the beginning and end of the period, and the length of the period  $K_v = \Delta R / (C_2H_4)^2 \cdot t$ . The units used were concentrations in terms of gram atoms of carbon per litre, and hours.

### The System Ethane: Ethylene-Hydrogen.

When pure ethane is heated to a temperature near to 600° it undergoes rapid primary decomposition into ethylene and hydrogen. The energy of activation of the process is about 75 K. Cal., so that, while at 600° equilibrium in the system ethane-ethylene-hydrogen is established almost instantaneously, at a little lower temperature there is considerable delay in the process. However, since on heating pure ethane there is a tendency to approach equilibrium with the products of primary decomposition, in studying the other thermal changes which occur when ethane is heated, over a range of temperature between 550° and 620°, it is convenient to use equilibrium mixtures of ethane, ethylene, and hydrogen, rather than pure ethane. Knowing the values of the equilibrium constants between the limits given above, any number of mixtures can be made up for any temperature, the limits of each series of mixtures being pure ethane on the one hand and pure ethylene on the other.

When Dr. L. E. Hockin and I commenced this investigation, in order to introduce some order into our work, we decided to investigate the properties of series of mixtures for which, in each series, the sum of the concentrations of  $C_2H_4 + C_2H_6$  was constant, while the ratio  $C_2H_4 / C_2H_6$  varied, the ratio,  $C_2H_4 \times H_2 / C_2H_6$  remaining constant. The work was continued by Dr. T. J. P. Pearce and myself and a summary of the whole of the results was published<sup>1</sup> last year.

When ethane, or one of the equilibrium mixtures which contains a considerable amount of hydrogen, and does not approach very close to the ethylene end of the series, is heated to between 550° and 620°, methane and condensation products are formed. Study of a very wide range of mixtures had shown that there is no direct connection between the formation of methane and of condensate. However, it seems that ethane takes part only in the reaction involving its primary decomposition, and that both the condensate ( $R$ ) and methane are derived, though by different processes, from ethylene.

We are not now concerned with the formation of methane, but reference must be made to the process by which it is formed. The rate of formation, in presence of hydrogen, appears to be proportional to the

<sup>1</sup> *J. Soc. Chem. Ind.*, 1934, **53**, 321-336T.

product of the concentration of the ethylene, and the sum of the concentrations of the ethane, methane, and hydrogen, activation resulting from collision of ethylene molecules with molecules of either of these species. Hydrogen concentration, at the higher temperatures, has some further effect on the rate of formation of methane. The addition of methane to an equilibrium mixture increases the rate of formation of methane from it, and the addition of other substances, such as silicon tetrafluoride has a similar effect.

For any series of equilibrium mixtures having the same total  $C_2H_4 + C_2H_6$  content, though the ratio  $C_2H_4/C_2H_6$  concentration varies considerably through the series, the rate of formation of condensate appears to be strictly proportional to the square of the ethylene concentration. The rate is not affected by the state of the surface of the reaction tube or by packing the reaction tube, at least at  $590^\circ$ , at which temperature the effect of surface was investigated. The effect of adding methane is negligible. However, when silicon tetrafluoride was added, the rate of formation of condensate was definitely increased.

Ignoring the fact last referred to, it would appear that the result-point to a simple bimolecular process, on the assumption that the total carbon in the condensate produced represents the carbon derived from a primary process involving two molecules of ethylene. There was experimental evidence to prove that neither methane nor any three-carbon product was associated with the formation of the condensate.

However, while the rate of formation of condensate was constant for each series of equilibrium mixtures at constant  $C_2H_4 + C_2H_6$  concentration, with fall in the total hydrocarbon concentration the value of the velocity constant tended also to fall, though the values obtained for very low hydrocarbon concentrations where the quantity of condensate was in any case very small, may be influenced by other factors, and need not be considered. Referring to Table I. in the paper by Dr. Pearce and myself, and taking as the mean values of  $K_p$  at any temperature and initial  $C_2H_4 + C_2H_6$  concentration, the means of the value set down against the longest period for each series under index letter and number, (since the individual values of  $K_p$  are the mean values from time 0 to  $t$ ), we have the following results:—

TABLE I.

Initial concentration $C_2H_4 + C_2H_6$	0.08	0.05	From graph, 0.05
620°	150.5	149	150
610°	139	130	118
590°	88	73	73
570°	—	40.5	43.5
550°	—	30	27

The values in the last column have been obtained by taking into consideration the fact that the data at  $590^\circ$  and  $620^\circ$ , in both cases with an initial concentration 0.05, are by far the most numerous and reliable, and plotting  $\log K_p$  against  $1/T$ . The method can only give an approximate value for the critical increment of the process, which is found to be 35.5 K. Cal. It is slightly different from that adopted in the original paper, but the result is the same. It leads to the important conclusion that, if the process is assumed to originate in bimolecular

collisions of ethylene molecules, the number of effective collisions is only one in 10,000 of the number indicated by the simple calculation.

Pease<sup>2</sup> determined the rate of condensation of ethylene between 350° and 500°, using a copper vessel, and working at pressures between 2 and 9 atmospheres. Under these conditions the rate of formation of methane is very small. The formation of condensate was found to follow a *square law*, and from the temperature coefficient the critical increment was found to be 35 K. Cal. However, by extrapolation it is found that the rate calculated from his data at 590° is 7.5 times as great as the rate found in our experiments on equilibrium mixtures. We carried out a few experiments at 400° in silica apparatus, and while we found that it was difficult to obtain reproducible results, the rate was much less than that found by Pease. It is suggested that Pease's data are influenced by the effect of the copper surface. Pease notes that the rate calculated is 1000 times that found by experiment.

It may be noted that at low temperatures the product is a mixture of chain hydrocarbons, which, from an experiment which Dr. Hockin and I carried out, seem to contain not less than eight carbon atoms. Near 600°, as might be expected, the products are aromatic. However, it seems likely that the rate of formation of condensate is the rate of the primary bimolecular process, and that subsequent processes do not involve the separation either of methane or of 3-carbon compounds, so that the measure of the initial rate is the amount of carbon separating as condensate, in whatever form it may ultimately appear.

Before commencing work on the equilibrium mixtures, Dr. Hockin and I had investigated the thermal behaviour of ethane. We found very great difficulty in obtaining reproducible results, and came to the conclusion that this was due to the effect of oxygen, adsorbed on the walls of silica reaction tubes, or even passing through the walls of the tubes, when they were thin. The difficulty was overcome by filling the reaction tubes with hydrogen, and heating to about 600° for some hours before introducing the ethane. The difference between the behaviour of different tubes seems to depend upon the extent to which primary decomposition of ethane is catalysed by the surface.

When ethane is heated, primary decomposition sets in at once, and as both the condensate and methane are derived from ethylene, the velocity of formation of these products should be zero at the start, and should increase as the ethylene content of the gas increases. This is actually what takes place, and the graphs which represent the rates of formation of both products show accelerated velocities. However, if we neglect the short initial period during which the concentration of the ethylene is increasing so rapidly that its mean concentration over the period cannot be computed, and calculate the values of  $K_p$  from the mean squared values of the ethylene concentrations, and the amount of condensate formed during consecutive intervals, we find that the value of the velocity constant tends to increase in a manner which has nothing whatever to do with the change in the ethylene concentration. When the process has proceeded for a certain time, which is about 3 hours at 590°, increasing at lower, and decreasing at higher temperatures, and diminishing generally at lower concentrations, either of two things may happen. At the higher temperatures the process suddenly slows down. At the lower temperatures the rate may slow down, or may be maintained so that the graph representing it is continuous. Graphs representing the process

at  $590^{\circ}$  and  $570^{\circ}$  are given in the paper referred to, and reproduced as Figs. 1 and 2 herewith, in which the crosses represent the results of experiments with plain reaction tubes at  $590^{\circ}$  and at  $570^{\circ}$ , respectively. It will be observed that at  $590^{\circ}$  the rates of formation of methane and of condensate are represented respectively by the graphs  $ab$ ,  $a'b'$ , which are discontinued after about three hours, but at  $570^{\circ}$  the graphs  $ab$ ,  $a'b'$ , are continued to  $c$  and  $c'$ . In both cases after  $bb'$  some of the points are below the continuation of  $ab$ ,  $a'b'$ .

An interesting point to be noted is that the phenomenon of acceleration of the rate of the reaction in the case of pure ethane is associated

FIG. 1.

both with the formation both of methane and of condensate. Also, after the period within which all the points representing the rates of formation of methane and of condensate lie on the slightly upward-tending graph, if in any experiment a low result is obtained for methane, a correspondingly low result is obtained for condensate. The only connection between the two processes is that both products are derived from ethylene, and this fact must be regarded as the key to the solution of this part of the problem.

Now ethylene is formed from pure ethane by a process which has an activation energy of 75 K. Cal., the thermal requirements of the process

being only 31 K. Cal., leaving a balance of 44 K. Cal. to be dissipated by the ethylene and hydrogen. The share of energy carried by the ethylene may be passed on, and by a process somewhat similar to that occurring in the degenerate chain system of Semenov, increases the rate of formation both of primary centres which result in the formation of condensate and also of those which lead to the formation of methane. By this process both the rate of formation of condensate and the rate of formation of methane can be increased. The cause of the slowing down of the

FIG. 2.

two processes has not been determined, but the rates after the breaks in the graphs seem to be close to the rates in the corresponding equilibrium mixtures.<sup>3</sup>

If we compute the rates for formation of condensate,  $K_p$ , for successive time intervals, omitting the first period, for which it is impossible to compute the concentrations of the ethylene accurately, and plot the values of  $K_p$  against the time from the zero time for the process, we find by extrapolation that the value of  $K_p$  for zero time, is not far from the mean

<sup>3</sup> *Lec. cit.*<sup>1</sup>, p. 333.

values for equilibrium mixtures at the corresponding ethane plus ethylene concentrations and temperature, but probably somewhat lower than

FIG. 3.

these values. This fact is demonstrated by the graphs in which represent the results of experiments with pure ethane, at 0.05 concentration, Fig. 3 at 590° (x empty tube, o tube packed with capillaries), and Fig. 4 at 570° (x plain tube, □ tube with two concentric linings). The values found

for equilibrium mixtures are 73 at 590°, and between 40 and 47 at 570°

Some experiments carried out with a view to finding out why, in experiments with pure ethane, in which the reaction tube had not been pre-treated with hydrogen, very erratic results were often obtained, had shown that the rate at which the primary decomposition of ethane took place varied with different tubes, and was most rapid in new silica tubes. In tubes which had the surface slightly increased by introducing two or three concentric lining tubes the effect was small, as indicated by Figs. 3 and 4, though it was noticed that the break in the graphs noted above was very marked. In Fig. 4 the points in squares were obtained using a tube containing two concentric tubes. However, when a tube was filled with capillary silica tubes<sup>4</sup> it was noticed that the equilibrium in the system ethane—ethylene—hydrogen (590°) was very rapidly established, and the rates of formation of methane and

FIG. 4.

<sup>4</sup> Loc. cit.<sup>1</sup>, p. 337, Tables XV., XVI., Fig. 7.

condensate showed only very slight acceleration. The results are represented by the circles in Fig. 3. If, as in these experiments, the primary decomposition of the ethane took place on the surface, the energy of the process might be dissipated more readily than in the gas phase.

The particular behaviour of pure ethane may be accounted for by supposing that the number of primary centres is increased owing to the fact that some of the molecules of ethylene formed by the primary decomposition of ethane carry energy which they contribute to the process by which the centres arise. The process is superimposed on the process involved in the formation of condensate from an equilibrium mixture, which one would like to regard as a simple one, involving activation by collision of two molecules of ethylene, which subsequently react. However, when one comes to study the formation of condensate from pure

FIG. 5.

ethylene, one observes some disturbing facts. I must admit that this part of the investigation has been neglected.

Fig. 5 represents the changes taking place when pure ethylene at initial concentration 0.05 gram atoms of carbon per litre is heated at 500°, the details being given in Table II. The process is obviously complex, for while the primary condensation process may be represented by

the rapid changes which follow result in the liberation of hydrogen, which takes part in secondary minor processes involving the formation of ethane and of methane.

Now the most obvious fact is that the rate of formation of condensate increases rapidly, while the concentration of the ethylene diminishes. One might expect that the initial rate, determined graphically, would give a value for the rate constant ( $K_p$ ) of about the same value as that

TABLE II.—EXPERIMENTS WITH PURE ETHYLENE.

obtained by the same method for equilibrium mixtures of the same initial concentration, and at the same temperature, *viz.* 73. However, the apparent value for the initial velocity is only about 20, and the real value may be considerably less. The mean calculated value for the period 0 to 5 minutes is about 31, and for the period 5 to 10 minutes about 107. The break occurs within the next five-minute interval, and during the two following 15-minute intervals the values are 60 and 98 respectively.

A very few experiments have been carried out with pure ethylene but they seem to indicate that the results are influenced to a considerable extent by the condition of the surface of the tube, and that it is difficult to obtain reproducible results. As soon as the apparatus, which is in use for other work, is available, the investigation will be followed up.

There are two possible alternative explanations of the behaviour of ethylene. In the first place we can assume that the process is initially a bimolecular one, and that the 4-carbon product resulting undergoes further association, and there seems to be direct chemical evidence that this process actually operates at low temperatures. The alternative is that a series of 2-, 3-, 4-carbon products are formed.

If we adopt the former alternative we must assume that the energy set free in the process,

is taken up by ethylene molecules, some of which contribute their share of the energy to the formation of new primary centres. The fact that in equilibrium mixtures the rate of formation of condensate is only 1/10,000 of the rate calculated on the assumption that the energy of activation is 35 K. Cal., making the usual assumptions as to molecular diameters, etc., suggests that the formation of condensate requires the dispersion of the energy of the bimolecular process by a third body. In the case of the equilibrium mixtures, the energy is taken up mainly by the ethane, and simply dispersed. In the case of pure ethylene, during the early stages, when only ethylene is present, the energy can only be taken up by ethylene molecules, and since these can react a chain process results. It seems likely that either of the mechanisms which operates in the case of pure ethane, or that which operates in the case of pure ethylene, disappears to a great extent in the case of equilibrium mixtures, which do not approach very closely to one end or the other of the series; for none of the phenomena associated with chain mechanisms are present. The increase of the rate of formation of condensate in equilibrium mixtures with increase in the total initial hydrocarbon content, may be due to increase in the rate of formation of primary centres, or to third-body action. Silicon tetrafluoride may exert a similar influence.

The primary step in the formation of condensate from ethylene appears to be a bimolecular process, the rate of which is influenced by several factors the nature of which has been discussed. There is no evidence as to how compounds of high molecular weight are formed for the primary product.

### The System Propane—Propylene—Hydrogen.

Sufficient work has been carried out in the neighbourhood of  $550^{\circ}$  to indicate the general course of the processes taking place. However, the problem is complicated by the fact that propylene decomposes in the presence of hydrogen yielding ethylene and methane, the mechanism being probably that suggested by Dr. Pearce and myself to account for the formation of methane from ethylene. At the same time two condensation processes take place, the primary steps in which may be represented by:—

The particular difficulty in the work, apart from the problem of analysis, which is certainly complex and tiresome, is due to the fact that we have always in the background the two equilibrium systems,

which, under the temperature conditions which are convenient for the investigation, appear to be partly heterogeneous, so that it is difficult to obtain reproducible results.

The work is important, particularly as it may throw light on the general questions involved in the cracking and condensation of hydrocarbons generally.

### Acetylene.

There is a considerable literature relating to this subject which is collected in a recent paper by Taylor and van Hook.<sup>5</sup> These authors

confirm the conclusion previously arrived at that the condensation process appears to be mainly bimolecular, but assume that the effect of hydrogen is to superimpose a bimolecular process involving hydrogen and acetylene. They explain the latter on the assumption that some of the acetylene

is hydrogenated, but make no attempt to ascertain whether this really happens or not. Their conclusions are based almost exclusively

<sup>5</sup> *J. Physic. Chem.*, **39**, 810.

on the results of pressure measurements at constant volume between 400° and 500°.

Dr. Hockin and I carried out a few exploratory experiments at 450°, using a silica tube of 35 c.c. capacity. In Table III. are the results at two concentrations.

The graph representing the first series showed a definite break in the middle, the first part being linear. The graph representing the second series is linear. That the slopes of the two graphs are nearly proportional to the squares of the initial concentrations may have no direct significance. The addition of hydrogen increases or decreases the velocity of the reaction, according to its concentration. When much hydrogen is added, some methane is formed, but apparently very little ethylene. The state of the silica surface has a considerable influence on the nature of the reaction.

These figures are quoted because I wish to make it clear that the mechanism of the polymerisation of acetylene is only likely to be explained when full experimental data are forthcoming. Speculations based upon measurements of changes of pressure are likely to confuse the real issues.

## ON TWO NEW POLYMERS OF ACETALDEHYDE.

By MORRIS W. TRAVLERS.

*Received 7th August, 1935.*

### 1.

Acetaldehyde, like many other organic liquids, dissolves very considerable quantities of air. For the purpose of studying the thermal decomposition of the liquid it was necessary to obtain it oxygen-free.

With this object in view, after drying over potassium sulphate, and fractionating using a long column, the temperature of which was controlled, the liquid was syphoned into the large bulb, A, of the apparatus shown in Fig. 1. The bulb was then cooled with solid CO<sub>2</sub> and alcohol, and the leading-in tube was sealed at *a*. The three bulbs had capacities approximately 500, 250, and 150 c.c. respectively, and they were partly filled with pieces of glass tubing. The apparatus was connected with a bulb which formed part of the apparatus for filling the reaction tubes for the thermal study, and through this apparatus, and a U-tube immersed in liquid oxygen, with a Töpler pump.

While the bulb A was cooled to near - 80° the whole apparatus was exhausted, and as acetaldehyde has a perceptible vapour pressure at this temperature, a little vapour condensed in the guard tube. The bulb A was then allowed to warm up to about - 60, and the bulb B was cooled in liquid oxygen, the Töpler pump being operated the whole time. While the liquid was distilling from A to B a considerable quantity of gas, mainly oxygen, was collected. When the bulb B was about two-thirds filled with liquid the connecting tube was sealed at *b*. During this operation both the bulbs A and B were cooled in liquid oxygen.

The bulb B was then warmed to about  $-60$ , and the bulb C was cooled in liquid oxygen. During the second distillation a little gas was collected, but when the bulb C was two-thirds filled with liquid the evolution of gas had practically ceased. The connecting tube was then sealed at *c*.

In the early operations part of the liquid was then distilled from C into D by the same process, but in later operations, for reasons to be mentioned directly, the final distillation was carried out by evaporating the liquid from air temperature into the receiving bulb cooled in ice. However, before sealing the connecting tube both bulbs were cooled with liquid air, to avoid decomposing aldehyde vapour.

Now we noticed that when air-free acetaldehyde was condensed at liquid air temperature, instead of obtaining a mobile liquid, the receiving bulb was found to contain a more or less viscous liquid or even a jelly. The viscosity of the product seemed to depend upon the extent to which

FIG. 1.

the air had been eliminated before the particular fraction was distilled, the content of the bulb B being less viscous than the contents of the bulb C, and the contents of C less viscous than the contents of D. If the contents of a bulb was viscous before redistilling, on distillation *in vacuo*, even from air temperature, it became more viscous, or even jelly like. However, the bulb D was connected with an apparatus by which its vapour pressure could be measured, and it was found that the vapour pressure of a jelly or viscous liquid was not measurably less than that of the mobile liquid.

If a bulb containing the viscous liquid was connected with an exhausted apparatus cooled to a low temperature, without admitting air in the process, the contents frothed, forming a vesicular mass, which, in time, settled down to an almost glassy material, apparently quite stable at the air temperature. At  $100^{\circ}$ , in a sealed tube, acetaldehyde was slowly regenerated.

I have had no opportunity of carrying out experiments with this substance, much less of investigating the mechanism of its formation. I have no intention of following up the study of it, and I should be glad to hear that someone else is doing so. It is clear from the method by which it is formed that air inhibits the process. Surface favours the formation of the jelly, and the state of the surface seems to be of some importance, for it was sometimes noticed that the jelly formed in particular regions of the surface of a bulb in which air-free acetaldehyde was condensed. It is most readily obtained by distilling air-free acetaldehyde into a bulb cooled in liquid air, the liquid evaporating from the air temperature.

The product seems to belong to the class called by Chalmers and others *macrocolloids*, which are formed by the addition of comparatively small units, successively, to form long molecular chains. To this class belong substances like rubber, and possibly cellulose. The energy of activation must be very small, if, indeed, the energy of activation comes into the picture at all. The inhibition of chain formation by gases must also be a physical process. On the other hand there must be a not inconsiderable free energy change accompanying the process of polymerisation.

## II.

(WITH MR. R. G. SOLLERS, B.Sc.)

The observations recorded above suggested an experiment on the polymerisation of acetaldehyde in presence of acid at low temperatures,

FIG. 2.

for though it is very well known that two compounds, metaldehyde and paraldehyde, are formed, literature tells us very little as to details. A small quantity of pure acetaldehyde was cooled to  $-80^{\circ}$ , and to the liquid was added a drop of an alcoholic solution of sulphuric acid. It was noticed that the contents of the tube containing the acetaldehyde solidified completely, but that, on warm-

ing to air temperature, very little metaldehyde could be separated by filtration. On distilling the liquid it was found to boil at  $73^{\circ}$ - $75^{\circ}$ , with some decomposition into aldehyde, and condensation to higher-boiling

products. Its molecular weight by the cryoscopic method was close to that corresponding to  $(C_2H_4O)_3$ ; and the vapour density determination at  $100^\circ$  showed that the compound had, initially, the formula given above, but that it dissociated rapidly.

The following experiments were carried out with a view to studying the formation of the substance. A quantity of acetaldehyde, 4.08 c.c. was placed in a test tube, and cooled to a definite temperature, which was either  $-38.5^\circ$ ,  $-78.5^\circ$  or  $-105^\circ$ , the latter being well above the melting-point of aldehyde, which is  $-125^\circ$ . A quantity of an alcoholic solution of sulphuric acid 0.08*N*, freshly made, was then run into the aldehyde from a pipette, the liquid being shaken. After remaining at rest at the temperature of the experiment for a fixed time, the liquid was warmed to the air temperature, and the metaldehyde was filtered off on a Gooch crucible, and, after washing with a few drops of alcohol, it was weighed. The data for three sets of experiments are represented by the graphs in Fig. 2, the quantities of metaldehyde formed being plotted against the strength of the acid added.

The whole process seems to be a very rapid one at any of the temperatures at which the results are recorded, for the time between adding the acid, and warming up and filtering the liquid made no perceptible difference to the quantity of metaldehyde formed. For equal acid strengths, between  $-105^\circ$  and  $-38.5^\circ$  the quantity of metaldehyde increases as the temperature rises, but, at higher temperatures still, the quantity decreases, and the liquid contains some paraldehyde.

The data refer to a single sample of acetaldehyde; but using a different sample, also supposed to be pure, for a series of experiments at  $-78.5^\circ$ , the graph representing the results had a slightly different slope. This suggests inhibition of one process or the other by a trace of some impurity.

The experiments throw no direct light on the problem of formation of either of the two bodies metaldehyde or paraldehyde, both of which are said to have the formula,  $(C_2H_4O)_3$ . It seems likely, that the first step is the formation of the dialdehyde,

and that a second step may be represented by,

the activation energy being derived from the first process. A somewhat inconclusive experiment indicated that a mixture of the dialdehyde with acetaldehyde did not yield metaldehyde. An alternative suggestion is that the primary formation of the dialdehyde is followed by rapid internal rearrangement, and the reasons for the stopping of the polymerisation process at the second and third stages respectively are really steric. Possibly the two alternatives are really identical.

*Bristol University.*

### GENERAL DISCUSSION.

Professor A. Staudinger (*Freiburg i Br.*) said: The very interesting polymerisation product of acetaldehyde which Professor Travers has just described is presumably a eucolloidal polyacetaldehyde. This can be concluded from the high viscosity and particularly from the elastic properties of this product, for such physical properties only arise in the case of very high molecular weight products of eucolloidal nature.

An analogous polymerisation product can be prepared by polymerisation of pure formaldehyde under conditions which are very similar to those of the polymerisation of acetaldehyde. In the polymerisation of formaldehyde in the presence of acid or alkali only hemicolloidal products of a polymerisation degree of approximately 100 are obtained and according to the reaction conditions  $\alpha$ -,  $\beta$ -, or  $\gamma$ -polyoxymethylenes.<sup>1</sup> These hemicolloidal polyoxymethylenes are powder-like substances. On the other hand in the polymerisation of pure formaldehyde one obtains a hard glassy mass which can also be got in the form of transparent films of remarkable strength.<sup>2</sup> When heated, this product becomes elastic and therefore it must be assumed that this product has a much higher degree of polymerisation than the hemicolloidal powder-like products, since only high molecular weight products of a degree of polymerisation of the order of 1000 and above possess elastic properties.<sup>3</sup> The molecular weight of this eu colloidal polyoxymethylene cannot, however, be determined, since the substance is completely insoluble. On account of this the new polyacetaldehyde which is soluble in organic solvents becomes very interesting. The differences in solubility between polyoxymethylene (polyformaldehyde) and polyacetaldehyde depend upon the fact that the former products have unbranched straight chains, whereas the polyacetaldehyde has methyl groups as side chains. The more irregular shape of the latter molecule is the cause of its greater solubility. Similar experiences were found in the case of the paraffins. Normal paraffins are scarcely soluble. The introduction of the methyl groups causes a considerable increase in their solubility so that the high molecular weight methyl substituted paraffins (compare also rubber) are soluble in organic solvents :<sup>4</sup>

# POLYMERISATION OF UNSATURATED HYDROCARBONS.\*

BY H. I. WATERMAN AND J. J. LEENDERTSE.

Received 19th July, 1935.

## Introduction.

The authors have sought to investigate how far the polymerisation phenomena of olefines under moderate conditions accord with true polymerisation. In certain special cases hydrocarbon mixtures poor in ring-compounds, in other cases products rich in ring-compounds may be required by industry. We had eventually, therefore, to study the conditions which are necessary to prevent molecular rearrangements and transformations which lead to the formation of saturated paraffinic hydrocarbon polymers on the one hand and of systems poorer in hydrogen on the other. The components rich in ring-compounds which are so often found in the reaction products, especially in the fractions of higher molecular weight, would be formed by the said rearrangements and transformations.

## Method of Investigation.

The usual methods were used in this investigation with the exception of a new method for the separation of the fractions of different molecular weight without any decomposition. For this purpose we applied the method of distilling in cathodic-ray vacuum tubes with internal means for the condensation of the distillate. The sum of the fractions thus obtained could be considered as representing the total original reaction product, no destruction having occurred during distillation. The fractions were investigated by the so-called "ring analysis," determining, *inter alia*, the specific refraction

and mean molecular weight and other physical constants of the saturated fractions. This method, which will be described more thoroughly in another paper<sup>1</sup> comprises also a careful non-destructive hydrogenation of the fractions obtained in polymerisation.

### Polymerisation of Ethylene.

Ethylene was polymerised under high pressure at 125°-150° C., with  $\text{AlCl}_3$  as catalyst and with pentane as a liquid diluent. The results of the experiments and the analysis of the fractions are represented in Fig. 1. The points in the figure relate to the completely hydrogenated fractions of the polymerisation product.

The fractions obtained from the free oil (A) were plotted on curve I., and, in addition, three fractions derived from the oil (B) liberated from the sludge after decomposition with ice water, were combined in curve II., as is indicated in the figure.<sup>2</sup> It was proved that the low boiling light fractions of the A oil without any further treatment were saturated and paraffinic,<sup>3</sup> which must be ascribed to an interchange of hydrogen. The higher fractions of the A oil are somewhat cyclic and the number of rings per molecule increases with increase of molecular weight. The fractions with a molecular weight of 250 to 350 contain on an average about one ring per molecule, whereas a fraction with the molecular weight 530 contains 2 rings per molecule. The B oil fractions are much richer in rings than the A fractions. The cyclic character is more dominating here, e.g., a product with molecular weight 365 contains more than 3 rings per molecule. An increase in molecular weight of the B fractions is connected with a stronger increase in the number of rings per molecule. A. W. Nash and Stanley<sup>2</sup> obtained analogous results. The advantage of the present investigation is that one gets a better survey of the nature of all the fractions, i.e., the cyclic character is determined by a number (compare Fig. 1).

The question might arise how far the cyclic character really is caused by the presence of rings. Could not the deviation of the specific refraction be explained by the presence of special branched hydrocarbons? In order to answer this question an ultimate analysis was carried out with a series of analogous fractions, from different polymerisation products of other olefines. It was thus proved that the inference derived from the specific refractive molecular weight diagram that the substances are cyclic is approximately correct, since this is in accordance with the ultimate analysis.

The observed presence of cyclic compounds may be explained by the considerations mentioned below:

(1) Aluminium chloride is a somewhat active catalyst and this factor, combined with a relatively high temperature 125-150° C., will increase the tendency of ring formation.

(2) Since we are using an olefine of low molecular weight, i.e., ethylene, the number of polymerisations and eventually connected rearrangements and transformations must be high if products of high molecular

<sup>1</sup> J. C. Vlughter, H. I. Waterman and H. A. van Westen, "Improved methods of examining mineral oils, especially the high boiling components," *J. Inst. Petr. Tech.*, July and August, 1935.

<sup>3</sup> The light boiling fractions boiling below about 100° C.

FIG. 1.

weight are formed. Therefore the chances of ring formation are better in this case than with olefines of higher molecular weight.

### Polymerisation of Isobutene.

It was proved that the polymerisation of isobutene with aluminium oxide on silica gel as catalyst at about 40° C. can be carried out practically without any formation of rings. The fractions were truly olefinic in nature and therefore after hydrogenation paraffinic in structure (compare Fig. 2). The curve which connects the different hydrogenated fractions lies close to the paraffin curve ( $C_nH_{2n+2}$ ).

Aluminium chloride seems to be an extraordinarily active catalyst when we consider that even at - 80° C. the reaction is nearly explosive. Several polymerisations were carried out at low temperature working at - 35° to - 40° C. and at + 7° to + 16° C. with pentane as a liquid diluent. It seems that the higher polymerised fractions in this case are somewhat cyclic. The curve which connects the hydrogenated fractions at higher molecular weight lies below the curve of the paraffins ( $C_nH_{2n+2}$ ).

Attention must be given to the fact that the fractions of high molecular weight are very sticky and viscous.

### Polymerisation of Pentenes.

The pentene experiments proved that aluminium chloride even at relatively low temperatures 0° to - 80° C. can cause a formation of rings. Experiments with normal 2-pentene at 0° C. yielded fractions which at a molecular weight of about 350 contained 1 ring per molecule. The branched pentenes at - 80° C. also yielded partly cyclic fractions.

An increase of the temperature to about 400° C. with or without alumina as a catalyst, causes an increase of the cyclic character of the polymerisation products of *n*-2-pentene, but with the branched pentenes, on the other hand, this influence if present, was smaller.

### Polymerisation of Hexadecene \* (experiments carried out by J. G. Frielink).

A polymerisation was carried out with boron fluoride as catalyst; the reaction temperature was 10 to 15° C., the duration of this experiment several hours. We worked with a stream of borium fluoride. The yield of polymers was 70 per cent. of the raw material. A second experiment was done with aluminium chloride, the temperature was 17-23° C., the duration of this experiment was 3½ hours, the proportion of catalyst used was 6 per cent., and it was added gradually. The yield was about 95 per cent. The results of the two experiments are represented in Fig. 3. In the first experiment the total reaction product was divided into three fractions of mean molecular weight 235, 460 and 728, determined after careful hydrogenation. In the  $AlCl_3$  polymerisation there was obtained only a product of high molecular weight 1482 after hydrogenation). In both experiments the hexadecene polymers proved to be free from cyclic compounds. It may be remarked that the viscosity-temperature curve for the hexadecene polymers, before and after hydrogenation, is more flat than the corresponding curves of isobutene and several pentene polymers.

\* The product obtained by decomposition of spermaceti, was probably a mixture of normal hexadecenes, not contaminated with branched olefines.

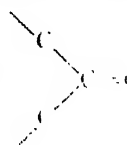

FIG. 3.

### Polymerisation of Cyclohexene.

In the polymerisation of cyclohexene at  $70^{\circ}\text{C}$ ., high molecular products were obtained, which after complete hydrogenation had a specific refraction in agreement with the calculated figures for cyclohexyl compounds of the same molecular weight. Thus, for example, at a molecular weight 400 the product contained about 5 rings per molecule. So in this case the observed phenomena may be explained by true polymerisation.

### Reaction Velocity of Polymerisation of the Olefines at $-80^{\circ}\text{C}$ .

The velocity of polymerisation depends on the molecular structure of the raw materials at  $-80^{\circ}\text{C}$ . especially, there are pronounced differences. It seems that if the double bond between two carbon-atoms

is connected with the structure , there is a marked increase

in the polymerisation velocity at  $-80^{\circ}\text{C}$ ., e.g., isobutene reacts at  $-80^{\circ}\text{C}$  much more strongly than the two normal butenes with aluminium chloride as a catalyst. Analogous differences are found with the homologues, although the reactivity generally decreases with increasing molecular weight.

### Summary.

Several fractions obtained by polymerisation of olefines, were completely hydrogenated and investigated by the so-called ring analysis method.

The number of rings for hydrogenated polymerisation fractions read in the specific refraction molecular weight diagram practically is in accordance with the results of ultimate analysis.

It was found that the formation of rings is connected with the polymerisation, especially for low molecular olefines with aluminium chloride as a catalyst, even at low temperature, e.g.,  $-80^{\circ}\text{C}$ .

True polymerisation not leading to ring formation was observed in the polymerisation of hexadecene at room temperature and with aluminium chloride and boron fluoride as catalyst.

Ring formation was not observed in the polymerisation of isobutene at  $40^{\circ}\text{C}$  with aluminium oxide on silica gel as catalyst.

By the polymerisation of cyclohexene products are obtained which seem to be completely cyclic, which is explained by true polymerisation.

At  $-80^{\circ}\text{C}$  with aluminium chloride as a catalyst the polymerisation velocity of olefines of equal molecular weight depends *inter alia* on the structure, the group

causes a higher activity than the group

Delft, Laboratory of Chemical Engineering,  
Technical University.

## GENERAL DISCUSSION.

**Dr. E. Bergmann** (*Rehoboth*) said: It is rather striking that the only ethylene homologue, the polymerisation of which does not lead to cyclic products is isobutene, containing one quaternary C-atom. All the others which have been investigated are of the type  $\text{RHC}=\text{CHR}$ . Since, on the other hand, it is known that  $\text{AlCl}_3$ , used by the authors as a catalyst, readily dehydrogenates organic compounds, the suggestion may be made that the formation of cyclic products is due to previous dehydrogenation to form either acetylenes or dienes, the former being polymerisable to benzenoid compounds, the latter to cyclic substances of the menthadiene type.

**Professor H. I. Waterman** (*Delft*), in reply, said: In the examples given for isobutene, the formation of rings was not important and can be explained by the consideration, that the temperature was very low in the experiments mentioned. The ethylene polymerisation experiments were done at a higher temperature (*e.g.*,  $125^\circ$  to  $150^\circ$  C.). The conditions (*e.g.*, temperature) have a striking effect on the molecular structure of the polymerisation products.

## THE MERCURY PHOTOSENSITISED POLYMERISATION OF ACETYLENE

BY H. W. MELVILLE.

*Received 10th July, 1935.*

Investigations on polymerisation processes have almost wholly been designed with a view to controlling the nature of the products of the reaction—a circumstance only to be expected from the importance polymeric substances have assumed in technical practice. On the theoretical side of the question little has been accomplished, for the good reason that the mechanism of the reactions undergone by comparatively simple molecules is still the subject of much controversy. At first sight it would appear to be impossible to attempt to analyse the mechanism of polymerisation of even the simplest molecules by means of the well-established methods of chemical kinetics. Kinetic methods are, however, not quite so restricted in their scope. Whilst their primary aim in dealing with complex reactions is to unravel the sequence of collision types which comprise such processes, much reliable information may be gathered from an examination of almost any complex reaction over a sufficiently wide range of operating conditions. In polymerisations there is fortunately a simplification which permits the analysis to be made more detailed than might otherwise have been the case. The properties of the growing polymer are certainly a continuous function of its size, so that, although a considerable number of different molecular species has to be considered, these molecules obey similar kinetic laws in their reactions with each other or with unpolymerised reactants. In this paper an attempt will be made to apply kinetic analysis to the polymerisation of acetylene in order to gain some idea of the type of collisions responsible for the initiation, propagation and cessation of the growth of the polymers.

A first step in elucidating the nature of polymerisation has been

taken by studying the molecular statistics of dimerisations. Vaughan<sup>1</sup> has shown that the dimerisation of ethylene, butadiene and isoprene are slow reactions in the sense that the observed bimolecular velocity constants are much smaller than those calculated from the measured energy of activation and supposing two square terms to supply the energy. This would imply that such molecules must be oriented in a particularly favourable position before association may occur. Since the dimerisation of simple molecules exhibit large steric factors, it is evident that such factors will play a part in the building up complex polymers.

The polymerisation of acetylene has been studied by a number of investigators. Berthelot and Gaudechon,<sup>2</sup> Bates and Taylor,<sup>3</sup> and Reinke<sup>4</sup> showed that when exposed to the full radiation of a "hot" mercury lamp, that is, under conditions where the mercury sensitised reaction is probably absent, acetylene is converted to an inert solid at room temperatures. In a similar way  $\alpha$ -particles<sup>5</sup> lead to polymerisation, the surprising result being that the number of molecules polymerised per ion pair is 20. Lind and Livingston<sup>6</sup> made the interesting observation that the quantum yield of the direct photochemical reaction is about nine, using a mercury lamp as source and paying particular attention to the exclusion of mercury vapour. Likewise in the electric discharge,<sup>7</sup> the number of acetylene molecules polymerised per ion pair is comparable with that obtained by the action of  $\alpha$ -particles. Not much is known about the product of the reaction except that its empirical formula is  $(C_2H_2)_n$ . It is noteworthy that the polymerisation is attended with little complication in respect of secondary decomposition, for no hydrogen or methane can be detected in the products (see below). The product must be of considerable molecular weight, for it is only sublimed in a vacuum of  $10^{-5}$  mm. with partial decomposition at temperatures in the neighbourhood of 300°. Kemula and Mzrzek<sup>8</sup> have, however, detected, spectroscopically, traces of benzene during the photochemical polymerisation at room temperatures. On prolonged illumination at 175-250° acetylene yields isolatable quantities of benzene besides a considerable amount of polymer.<sup>9</sup> Acetylene also polymerises<sup>10</sup> if heated above 400° at a pressure of several hundred millimetres, but the kinetic interpretation of the data is rather difficult.

Ethylene too may be polymerised by exposing to the full radiation of the mercury lamp<sup>2</sup> or by collisions with excited mercury atoms.<sup>11</sup> The reaction is more complicated than that of acetylene. It has been shown qualitatively<sup>12</sup> that both methods of stimulation yield acetylene as primary products and therefore it is not improbable that the real polymerisation reaction is that of acetylene, the polymer of which is

simultaneously reduced by the hydrogen liberated in the primary dissociation. In the thermal reaction ethylene, unlike acetylene, appears only to form dimers after which the process stops.

In the following pages the above-mentioned experiments have been extended by examining further the polymerisation of acetylene and ethylene under the influence of excited mercury atoms. An attempt is then made by combining older data with the new, to gain some general idea of the type of collisions responsible for the formation of the polymer.

### Experimental.

Several types of reaction vessel were used. The final arrangement adopted consisted of a silica bulb attached to a small mercury diffusion pump<sup>13</sup> to circulate the gas through traps, the inner surface of which was coated with mercury droplets. This precaution was taken in order to keep the mercury vapour pressure at a constant value, for there is evidence that part of the mercury is removed as a result of polymerisation. To avoid imprisonment<sup>14</sup> of resonance radiation the mercury vapour pressure was not allowed to exceed 0.0003 mm. Another similar reaction vessel completely filled with silica tubes, their axes being set parallel to that of the reaction tube, was employed for experiments on the effect of the proximity of surfaces on the rate of polymerisation. The reaction bulb was placed in a furnace for experiments above 20° and a silica lens projected an approximately parallel beam of light into the reaction tube.

Deposition of polymer on the walls of the reaction vessel cuts down the intensity of light entering the gas and therefore measurements were restricted to low pressures (< 10 mm.) to avoid large corrections on account of this factor. Pressures were measured by a McLeod and a Bourdon gauge. Acetylene was taken from a cylinder and passed slowly through a trap at - 80° in order to remove the greater part of the accompanying acetone. The gas was then subjected to repeated fractionation *in vacuo*, the first fractions only being retained. Ethylene from a cylinder was first passed over  $P_2O_5$  and then fractionally distilled in the same manner as acetylene.

### Results.

#### Effect of Mercury Vapour Pressure.

Preliminary experiments were made with a 100 c.c. bulb attached to a mercury reservoir by a 1 mm. capillary 30 cm. long, no circulating pump being employed. With this arrangement the pressure-time curves consistently exhibited an initial rapid decrease, thereafter the reaction proceeds smoothly as is shown by curves I and II in Fig. 1. Further repeated fractionation of the acetylene failed to remove the abnormality. It was not due to oxygen, for when 10 per cent.  $O_2$  were added the pressure-time curve assumes the shape shown by curve III. Acetylene was polymerised in the bulb and after the initial fast rate of reaction was completed, a further dose of acetylene was admitted; the rapid initial rate was once more obtained. The falling off in rate might be due to an inhibitor. 0.85 mm. of acetylene were admitted, 0.60 mm. being polymerised (curve I). The acetylene was then withdrawn from the insulation vessel which was pumped out. Next the acetylene was condensed into a liquid air trap and subsequently allowed to evaporate slowly into the reaction vessel, the final portion being retained. On switching on the light, however, the initial rapid rate was once more observed (curve II). Finally the mercury vapour pressure was increased to 0.001 mm. when an immediate increase in velocity of polymerisation occurred (curve IV). A similar rapid decrease

<sup>13</sup> Melville, *J. Chem. Soc.*, 1934, 1244.

<sup>14</sup> Melville, *Proc. Roy. Soc.*, *in the press*.

in rate also obtains with high mercury vapour pressures. These observations suggest that the falling off in rate is due to a diminution of mercury vapour pressure as a result of chemical participation of mercury atoms in the polymerisation reaction. An adequate supply of mercury vapour to maintain the velocity is prevented by the narrow capillary. On putting into operation a reaction system in which the mercury reservoir was close to the insulation tube, the initial kink in the pressure-time curves completely disappeared, thus supporting the indirect evidence obtained above (curves V, VI, VII). This is the reason for utilising a circulatory system when the reaction tube is in a furnace and the mercury reservoir is necessarily at some distance from the zone of reaction.

Fig. 1

The conclusion is therefore that mercury atoms are removed during the mercury sensitised polymerisation of acetylene. It is probable that an excited atom on colliding with acetylene forms a complex of the acetylide type which initiates the polymerisation reaction.

#### Effect of Acetylene Pressure.

At the comparatively low pressures at which these measurements are made, an appreciable fraction of the excited mercury atoms radiate and hence the rate of polymerisation will decrease with diminishing pressure due to this factor alone. Any additional variation, on account of factors operative in the polymerisation itself, will therefore be superposed on processes connected with mercury atoms. The rate of polymerisation may therefore be represented by

$$-\frac{d[C_2H_2]}{dt} = f(P) \cdot k[Hg^*][C_2H_2],$$

where  $f(P)$  is that part of the polymerisation process subsequent to the collision of the mercury atom and acetylene molecule. This equation, on allowing for radiation of mercury atoms, becomes

$$-\frac{d[C_2H_2]}{dt} = f(P) \cdot K \cdot \frac{k[C_2H_2]}{k[C_2H_2] + 1/\tau},$$

where  $K$  is a constant depending on the light intensity and on the mercury vapour pressure.  $\tau$  is the life-time ( $10^{-7}$  secs.) of the excited atom. The variation of rate from a pressure of 0.01 to 10 mm. is shown in Fig. 2.

Fig 2

Up to about 0.5 mm. the rate increases with the first power of the pressure. At higher pressures the curve begins to bend round, apparently approaching a maximum. This is better shown by Fig. 3 where the reciprocal rate is plotted against reciprocal pressure giving a linear relation. These are, however, just the relationships to be expected if the factor,  $f(P)$ , in the above equation is independent of acetylene pressure. The growth and the cessation of growth must therefore be independent of acetylene pressure.

#### Effect of Temperature.

The following results were obtained at different temperatures (Table I.) where it will be seen that the rate of polymerisation increases to a flat maximum, thereafter decreasing. Above 500° the polymer begins to decompose with the production of hydrogen so that measurements cannot be reliably made. Below 500° polymerisation is unaccompanied by appreciable decomposition and there is no hydrogen or methane produced during polymerisation. Nor was there any formation of measurable quantities of substances less volatile than acetylene, such as benzene. Pressures were adjusted to give constant concentrations of acetylene in the

reaction bulb. The increase in reaction rate is not due to any increase in the efficiency of collisions of excited mercury atoms with acetylene, for such efficiencies are known to be practically independent of temperature.<sup>13</sup>

#### Effect of Surfaces.

The experiments in Table I show that so far as the relative rates compared to 27 are concerned, the effect of packing the reaction tube is small. The effect of packing was further investigated at 20 at higher intensities. For example in one set of experiments with an initial pres-

Fig 3

sure of 4 mm., the rate in the empty tube was 0.007 mm./min. and in the packed tube 0.050 mm./min. Fig. 4 shows a complete series of experiments at different pressures and at a temperature corresponding to the maximum rate at which polymerisation occurs. First it will be seen that the rate in the empty tube is on the average 1.6 times faster than in the packed tube. The two lines labelled bimolecular and unimolecular indicate how the rate of polymerisation would vary if it were respectively bi- and unimolecular. The close parallelism of the results to the unimolecular line is in agreement with the data at 20° (p. 262) at lower values of the chain length. At pressures less than 0.05 mm. in the packed tube and to a less extent in the empty tube appreciable thermal decomposition of the

<sup>13</sup> Cf. e.g. Cario and Franck, *Z. Physik*, 1926, **37**, 619.

polymer occurred with the production of hydrogen and methane, so that reliable measurements of the effect of pressure on the polymerisation could not be made.

Though the polymer is deposited on the walls, the walls do not retard nor accelerate its growth once that is started by excited mercury atoms. Had the chains been stopped at the surface the decrease in rate on packing the vessel would have been  $(5/0.7)^2 = 50$  times.

#### Effect of Intensity.

For this purpose two lamps were arranged to illuminate the same part of the reaction tube at about equal intensities. Three runs were made: (a) lamp 1, (b) lamps 1 and 2, (c) lamp 2. In Table II. two experi-

Fig. 4

ments, one at high and the other low pressure, are given to show that the rate of polymerisation due to both lamps operating simultaneously is nearly equal to that when operated separately. This means that the rate of polymerisation is proportional to the rate at which the chains are started.

#### The Propagation of the Polymerisation in Space.

The polymer may easily be rendered visible by gentle heating *in vacuo* when it carbonises to a darker deposit, thereby fulfilling a useful purpose. Whereas the temperature coefficient of the rate of polymerisation might be able to yield an approximate estimate of the efficiency of the reactions involved, there is a complication in that it is a composite coefficient describing both propagation and termination reactions. An alternative method

of measuring the efficiency of the propagation reaction was therefore necessary. The following device was adopted. A clean cylindrical reaction vessel 5 cm. long and 5 cm. in diameter was fitted with a band of tin foil 1 cm. wide around the middle (Fig. 5). The mercury vapour pressure was raised to 0.001 mm. so that 50 per cent. of the resonance light was absorbed in penetrating through 2 mm. of vapour, the zone of initiation of the polymerisation being thereby confined to a region close to the walls. The mercury lamp was placed about 10 cm. from the reaction vessel opposite the foil. On carrying out the polymerisation at high pressure—10 mm.—it was observed that only the side of the reaction vessel facing the lamp became covered with polymer. The zone of reaction

must then be confined to a region close to the wall—an observation further supported by the fact that there was no visible trace of the deposit behind the tin foil. This was most easily observed by heating the whole of the bulb to carbonise the deposit, admitting oxygen and applying a fine pointed flame along a line parallel to the axis of the tube (Fig. 5a). A small portion of the wall was thus cleared of polymer in order to serve as a control in visually estimating the density of deposit. As the pressure is lowered the zone of initiation remains the same, but the zone of polymerisation will

extend further into the bulb. At 6.71 mm., 1.35 mm. of acetylene being polymerised, no visible trace of the deposit could be detected at more than 1 mm. from the edge of the foil. On reducing the pressure to 0.9 mm., depositing 2 mm. of acetylene in successive runs, the deposit had crept distinctly behind the foil, but the middle point was still clear of polymer (Fig. 5b). Finally at 0.1 mm. the deposit appeared to be fairly evenly distributed behind the foil (Fig. 5c), although the density of deposit was not so great as that on the parts of the bulb directly exposed to the lamp. At a pressure of 1 mm. therefore the building up of the polymer occurs during a time in which the chain has diffused a distance of a few millimetres. A molecule of normal dimensions will diffuse through

FIG. 5

a layer of 1 cm. of acetylene at 1 mm. pressure in about  $10^{-3}$  sec., during which it experiences about  $10^4$  collisions. If the chain length is 10, reaction occurs once in every  $10^3$  collisions, which in turn corresponds to an average energy of activation of 4000 cal., if only two square terms were involved.

This shadow method can also be applied to the question whether polymer is selectively deposited on a surface already covered. Starting with a clean bulb having the strip in position, about 0.010 mm. of acetylene were polymerised. The strip was then removed and 2 mm. of  $C_2H_4$  polymerised at a pressure of 6 mm. On carbonisation no selective deposition of the polymer could be observed.

### Ethylene.

A number of experiments were also made with ethylene. They serve to demonstrate that the polymerisation of this molecule occurs by rather an indirect mechanism. In agreement with preliminary experiments of Olson and Meyers<sup>11</sup> it was observed that on first illuminating ethylene at 20° there was a marked *increase* in pressure, followed later by a decrease, there being a residual pressure on prolonged exposure. The initial increase becomes more predominant as the pressure of ethylene is lowered, and for a given intensity of light the maximum is reached more quickly at low pressures. The following figures show the magnitude of these effects:—

Press. of $C_2H_4$ . . .	9.88	6.83	4.65	2.36	1.61	0.19	0.11	0.003
Max. increase in tot. press. . .	0.63	0.41	0.35	0.10	0.22	0.041	0.031	0.024
Max. increase $C_2H_4$ .	0.064	0.060	0.076	0.081	0.136	0.215	0.28	0.38
Time for increase (min.) . .	10	9	6	5	2.5	18	15	20

The increase is due to the production of gas non-condensable in liquid air. Since the pressure of gas condensable in liquid air remains constant the non-condensable gas must be hydrogen. The ethylene then is first dissociated into hydrogen and acetylene. The latter will polymerise as described in the previous pages. The hydrogen pressure does not continue to rise but gradually reaches a maximum, as is shown by Fig. 6. Here the results of a series of experiments starting with identical  $C_2H_4$  concentrations have been plotted to indicate the total pressure, pressure of hydrogen and of condensable gas. The hydrogen must be consumed in the hydrogenation of the acetylene polymer since the decrease in total pressure shows that ethane, arising out of the hydrogenation of ethylene by atomic hydrogen, cannot be a final product of the reaction. Making the assumption that after the maximum in the total pressure time curve is attained, the acetylene and hydrogen disappear in equimolecular amounts, it then becomes possible to plot on the same diagram the pressure of ethylene and of acetylene during the whole course of polymerisation. The final ethylene polymer may thus be regarded as a hydrogenated polymer of acetylene. The polymerisation of ethylene is therefore not a chain reaction like that of acetylene because every molecule polymerised must first have been dissociated by a collision with an excited mercury atom. The difference between the acetylene and ethylene reactions is further emphasised when their temperature coefficients are compared. The rate of ethylene polymerisation is practically unaffected by raising the temperature from 27° to 280°, compared with an approximately 10-fold increase with acetylene. For example, at 2.01 mm.  $C_2H_4$  and 27° the rate of the initial increase of pressure was 0.08 mm. per min. and at 280° at a pressure of 4.13 mm., 0.07 mm./min. It is noteworthy that even at elevated

temperatures the molecule which initiates polymerisation of acetylene does not induce the polymerisation of ethylene, which is not surprising having regard to the fact that ethylene itself only forms a dimer at higher temperatures, whereas acetylene polymerises to a variety of products.

The behaviour of acetylene may be briefly recapitulated :

(1) Acetylene is polymerised at  $20^{\circ}\text{C}$ . to a substance whose formula is approximately  $(\text{C}_2\text{H}_2)_n$  by ultraviolet light, excited mercury atoms and  $\alpha$ -particles. Each type of stimulus induces the reaction of several molecules of acetylene.

(2) The chain length ( $\nu$ ) is independent of pressure from 0.1 to 760 mm., independent of the rate at which chains are started and independent of the diameter of the reaction tube.

FIG. 6.

(3)  $\nu$  increases from about 10 at  $20^{\circ}$  to about 100 at  $250^{\circ}$ , at which temperature it is a maximum and tends to decrease above  $250^{\circ}$ . The initial increase in  $\nu$  with temperature corresponds to an energy of activation of 4000 cal.

(4) By measuring the distance of propagation of the chains in space, the average energy of activation for propagation amounts to not more than 4000 cal.

### The Mechanism of the Reaction.

Since the reaction is of the chain type in the sense that one activated molecule of acetylene may induce the reaction of several others, the polymer must in the first instance be built up by the successive addition of acetylene molecules. The molecular weight of the polymer ought therefore to be equal to the chain length multiplied by the molecular weight of acetylene. At  $20^{\circ}$  the chain length is 10 and the empirical

formula should be  $(C_2H_2)_{10}$ . Hydrocarbons containing 20 carbon atoms are volatile on heating to 200-300° in a high vacuum. The acetylene, however, partly decomposes when attempts are made to sublime it. This would appear to suggest that there is some secondary polymerisation of the products of the gaseous chain reaction.

The chain length is finite and therefore a reaction must come into play which prevents further addition of acetylene molecules. There are three types of collision which might be responsible for this phenomenon. (1) Two polymers mutually destroy each other in so far as further addition of acetylene is concerned. (2) A collision between an acetylene molecule and the polymer, of a different character to the propagating collision, deactivates the latter. (3) The chain carrying polymer is spontaneously deactivated. Deactivation cannot occur at the walls since packing the reaction vessel does not diminish the chain length.

The consequences of the second type of collision may now be considered in order to show how it is possible to treat the problem of polymerisation by the principles of chemical kinetics. To obtain the rate of polymerisation the concentration of each of the transitorily occurring polymers must be known and in addition their velocity coefficients of reaction with acetylene. Fortunately a certain amount of simplification arises automatically. Let  $I[C_2H_2]$  be the rate at which acetylene molecules are activated, the activated molecules being denoted by  $[C_2H_2]_1$ .  $k_1[C_2H_2]_1[C_2H_2]$  is the rate at which acetylene molecules add on to activated acetylene and  $k'_1[C_2H_2]_1[C_2H_2]$  the rate at which such molecules are deactivated. Then for each polymer molecule there will be a stationary state equation

$$\frac{d[C_2H_2]_1}{dt} = I[C_2H_2] - k_1[C_2H_2]_1[C_2H_2] - k'_1[C_2H_2]_1[C_2H_2] = 0,$$

$$\frac{d[C_2H_2]_2}{dt} = k_1[C_2H_2]_1[C_2H_2] - k_2[C_2H_2]_2[C_2H_2] - k'_2[C_2H_2]_2[C_2H_2] = 0,$$

$$\frac{d[C_2H_2]_n}{dt} = k_{n-1}[C_2H_2]_{n-1}[C_2H_2] - k_n[C_2H_2]_n[C_2H_2] - k'_n[C_2H_2]_n[C_2H_2] = 0.$$

Adding these equations,

$$I[C_2H_2] = k_n[C_2H_2]_n[C_2H_2] + \{k'_n[C_2H_2]_n + k'_{n-1}[C_2H_2]_{n-1} + \dots + k'_1[C_2H_2]_1\}[C_2H_2],$$

$$I = k_n[C_2H_2]_n + \{k'_n[C_2H_2]_n + \dots + k'_1[C_2H_2]_1\}.$$

Solving each equation for the value of  $[C_2H_2]_n$ ,

$$[C_2H_2]_1 = \frac{I[C_2H_2]}{k_1[C_2H_2] + k'_1[C_2H_2]} = \frac{I}{k_1 + k'_1},$$

$$[C_2H_2]_2 = \frac{k_1[C_2H_2]_1[C_2H_2]}{k_2[C_2H_2] + k'_2[C_2H_2]} = \frac{k_1}{k_2 + k'_2} \cdot \frac{I}{k_1 + k'_1},$$

$$[C_2H_2]_3 = \frac{I}{k_1 + k'_1} \cdot \frac{k_1}{k_2 + k'_2} \cdot \frac{k_2}{k_3 + k'_3},$$

$$\dots$$

$$[C_2H_2]_n = \frac{I}{k_1 + k'_1} \cdot k_1 \dots \frac{k_{n-1}}{k_n + k'_n}.$$

Hence

$$-\frac{d[\text{C}_2\text{H}_2]}{dt} = I[\text{C}_2\text{H}_2] + [\text{C}_2\text{H}_2][\text{C}_2\text{H}_{2,1}\{k_1 + k'_1\} \\ + [\text{C}_2\text{H}_2][\text{C}_2\text{H}_{2,2}\{k_2 + k'_2\} + \dots + [\text{C}_2\text{H}_2][\text{C}_2\text{H}_{2,n}\{k_n + k'_n\}.$$

Whence, substituting for the values of  $[\text{C}_2\text{H}_{2,n}]$ ,

$$-\frac{d[\text{C}_2\text{H}_2]}{dt} = [\text{C}_2\text{H}_2] \left\{ 2I + \frac{I}{k_1 + k'_1} \cdot k_1 + \dots \right. \\ \left. + \frac{I}{k_1 + k'_1} \cdot \dots \cdot \frac{k_{n-1}}{k_n + k'_n} (k_n + k'_n) \right\}, \\ \nu = -\frac{d[\text{C}_2\text{H}_2]/dt}{I[\text{C}_2\text{H}_2]} = 1 + \left\{ 1 + \frac{k_1}{k_1 + k'_1} + \dots \right. \\ \left. + \frac{k_1}{k_1 + k'_1} \cdot \frac{k_2}{k_2 + k'_2} \cdot \dots \cdot \frac{k_{n-1}}{k_{n-1} + k'_{n-1}} \right\}. \quad (\text{A})$$

or generally

$$\nu = \sum_0^{n-1} \{ (1 + k' / k) \}^{-1} + 2.$$

If the chain stops by the spontaneous decomposition of the polymer molecule, the last term in the equation for the stationary concentration of the various carriers becomes  $k_1''[\text{C}_2\text{H}_{2,1}][\text{C}_2\text{H}_2]$ , etc. Proceeding in the same way it may be shown that

$$\nu = 1 + \{ 1 + k_1'' / k_1 [\text{C}_2\text{H}_2] \}^{-1} + \dots \\ + \{ 1 + k_1'' / k_1 [\text{C}_2\text{H}_2] \}^{-1} \cdot \dots \cdot \{ 1 + k_n'' / k_n [\text{C}_2\text{H}_2] \}^{-1},$$

$$\text{or} \quad \nu = \sum_0^n \{ (1 + k'' / k [\text{C}_2\text{H}_2]) \}^{-1} + 1,$$

and hence  $\nu$  will be proportional to the acetylene pressure.

Finally consideration of the mutual destruction of the polymer carriers gives an equation showing that the chain length is a function of the rate of starting and of the acetylene pressure. The experimental data definitely support the first mechanism, that is, termination occurs in a collision between a growing polymer and acetylene, for  $\nu$  is independent of  $[\text{C}_2\text{H}_2]$  and of  $I$ . But this is also the propagating type of collision and therefore there must be two kinds of collision—one for propagating the growth of the polymer and the other for stopping it. The next question is to separate the two types.

As a first approximation it will be assumed that  $k'_1 / k_1 = k'_2 / k_2 = x$ . Equation (A) becomes

$$\nu = 1 + \left( 1 + \frac{1}{1+x} + \frac{1}{(1+x)^2} + \dots \right).$$

If  $x$  is not too small this series converges rapidly and summing to  $\infty$  terms,

$$\nu = 2 + 1/x.$$

$x$  cannot be unity, for  $\nu$  is greater than 3. If the chains are long,

$$\nu = k/k' = \alpha/\alpha', \quad \epsilon = (E - E')/RT,$$

where  $\alpha$  and  $\alpha'$  are coefficients incorporating steric factors and square terms (if more than two square terms are involved in the collisions). At  $20^\circ$ ,  $\nu = 10$  and  $E - E' = 4000$  cal.  $\alpha/\alpha'$  is then  $8 \times 10^3$ . Considering the steric factor first, it is probable that only a small portion of the polymer molecule has the property of adding on an acetylene molecule. On the other hand, two possibilities may be distinguished in the termination collisions. (a) The acetylene molecule on colliding with the polymer disintegrates it into fragments incapable of further propagating the chain (steric factor large compared with that in propagating collision). (b) The acetylene molecule becomes attached to that position at which growth of the polymer normally occurs, but a rearrangement of bonds takes place such as to prevent the further addition of acetylene (steric factors for propagation and termination equal). If steric factors alone controlled the magnitude of  $\alpha/\alpha'$  then  $\alpha'$  would be equal to or greater than  $\alpha$ . The factor expressing the increased rate of activation due to the participation of more than two square terms in the activation process is

is  $\frac{1}{(s/2 - 1)!} (E/RT)^{s/2 - 1} + \frac{1}{(s/2 - 2)!} (E/RT)^{s/2 - 2}$ , since  $E/RT$  is not very large,<sup>16</sup> ca. 10.  $E$  is greater than  $E_1$  and hence the square term factor for propagation will be greater than the termination factor if  $s > s'$ . If further  $s > s'$  then the ratio of propagation to termination factor will decrease with temperature and will therefore tend to compensate for the increase brought about by the simple energy of activation factor  $e^{-(E - E')/RT}$ , thus making the chain length finally independent of temperature. If  $x$  is a function of the size of the polymer, this will make the series expressing the chain length converge more rapidly, but the suggested explanation of the maximum in the chain length—temperature curve remains as before.

According to the treatment given above, the average molecular weight of the polymer will be equal to  $\nu \cdot M_{C_2H_2}$ , but since there is a finite probability that the chain will be stopped at any link, the molecular weight of the products of the chain reaction will theoretically extend from  $1 \cdot M_{C_2H_2}$  to  $\infty M_{C_2H_2}$ . When  $x$  is a function of the size of the polymer, however, the tendency for the formation of polymers of high molecular weight will be curtailed.

### Summary.

The mercury photosensitised polymerisation of acetylene has been studied at pressures from 0.05 to 10 mm. and at temperatures from  $20^\circ$  to  $500^\circ$  C. with the following results:

The excited mercury atoms form, with an acetylene molecule, a complex, which then adds on further acetylene molecules thereby producing a polymer by a chain mechanism. The chain length (no. of acetylene molecules polymerised per excited mercury atom deactivated by acetylene) is independent of acetylene pressure, of the rate at which chains are started and is not affected by packing the reaction bulb. The chain length (10 at  $20^\circ$ ) increases to 100 at  $250^\circ$ , thereafter decreasing.

These kinetics are shown to be consistent only with the assumption that the cessation of the growth of the polymer is due to a collision of an acetylene molecule with the growing polymer but of a different kind to that responsible for propagation.

Ethylene also polymerises under the same conditions, but it would appear that the first stage is the dissociation to hydrogen and acetylene

<sup>16</sup> Hinshelwood, *Kinetics*, p. 24, 3rd edit.

followed by the polymerisation of acetylene and finally the partial hydrogenation of the acetylene polymer.

The author wishes to thank Prof. E. K. Rideal for suggesting this investigation and for many helpful discussions during its progress. He is also indebted to the Royal Commissioners for Exhibition of 1851 for a Senior Studentship.

## THE POLYMERISATION OF PHOSPHORUS.

BY H. W. MELVILLE AND S. C. GRAY.

*Received 10th July, 1935.*

It is generally conceded that, of the two allotropic modifications of phosphorus, the red one is a polymer. How the polymer is constructed and from what size of unit is not very clearly defined in the few papers<sup>1</sup> on the subject. Attempts have been made to measure its molecular weight and it is suggested that this is  $P_8$  or even higher.<sup>1</sup> Much work, too, has been carried out on the conditions necessary for the reversible transformation white  $\rightleftharpoons$  red to proceed. In so far as the equilibria of the system are concerned, the position may be regarded as satisfactory in its main outlines.<sup>2</sup> With regard to the constitution of white phosphorus there is, for the present purpose, not much doubt. It dissolves in solvents such as carbon disulphide in units of  $P_4$  and its vapour density also shows that  $P_4$  molecules are in equilibrium with the solid.

No attempts have, however, been made to elucidate the nature of the transformation nor of the constitution of red phosphorus (if it is a polymer by the methods of chemical kinetics, probably because the system is not an easy one to work with. The vapour pressures of both modifications are small at  $15^\circ\text{C}$ . and even their ratio at high temperatures is rather high, only attaining equality at the inconvenient pressure of 41 atmospheres.

The present paper therefore describes an attempt to apply kinetic concepts to the problem. During the course of some experiments on the heterogeneous initiation of reaction chains in phosphorus-oxygen mixtures at low pressures by means of a tungsten filament,<sup>3</sup> it was frequently observed that the reaction bulb became covered with a film of red phosphorus. It was noteworthy, moreover, that the deposit often appeared at some considerable distance from the zone of reaction, even penetrating into narrow capillaries. Apparently besides catalysing the chain reaction, the tungsten could in some way transform phosphorus-vapour to red phosphorus, for the red deposit is not formed if phosphorus and oxygen are allowed to combine spontaneously at pressures only slightly higher than those employed for the stable chain reaction.

<sup>3</sup> Melville and Ludlam, *Proc. Roy. Soc.*, 1932, **A135**, 315.

Similar deposits of red phosphorus, unaccompanied by white phosphorus or phosphorus vapour, are obtained when phosphine is decomposed by light of  $\lambda < 2300 \text{ \AA}$ ,<sup>4</sup> by excited mercury atoms,<sup>5</sup> or on the surface of tungsten or molybdenum.<sup>6</sup> By passing a stream of  $P_4$  molecules through a silica jet at  $500\text{--}800^\circ$  in the apparatus shown in Fig. 1. circular deposits of red phosphorus may be collected on a glass surface cooled to  $-80^\circ$  and of an area to be expected from the geometry of the jet system. Summarising then, it appeared that if  $P_4$  molecules be heated to a high enough temperature, or if phosphorus be formed in the decomposition of phosphorus containing molecules, it is invariably deposited as the red modification.

At room temperatures, red phosphorus has a negligible vapour pressure and therefore the transformation in presence of a tungsten filament seemed to a comparatively simple type of heterogeneous reaction which might help to throw some light on the manner in which red phosphorus is deposited and also on the constitution of red phosphorus itself.

FIG. 1.

Another problem on which a simple heterogeneous reaction of this nature might be able to yield some information is as follows. In certain heterogeneous reactions, the collision efficiency of the reactant molecule happens to be approximately equal to  $e^{-E/RT}$  where  $E$  is the apparent energy of activation as measured by the temperature coefficient of the reaction velocity.<sup>7</sup> Such a relationship, though probably fortuitous, would imply that molecules merely collide with the surface, abstract from it an energy equal to or greater than  $E$  and react forthwith. If such were the case, molecules possessing in the gas phase energy rather greater than the average would react more readily since they do not need to acquire so much energy from the surface. In other words, the energy of a molecule in the gas may contribute to the energy of activation derived from the surface and so aid its decomposition thereon.

<sup>5</sup> *Ibid.*, 1932, A138, 374.

<sup>6</sup> Melville and Roxburgh, *J. Chem. Soc.*, 1933, 586.

<sup>7</sup> See e.g., Hinshelwood, *Kinetics*, p. 360.

At high pressures, and with filament catalysts, it is difficult to disentangle such effects because there is a region of gas round the filament at the same temperature as the filament itself. In point of fact, reactions are known<sup>8</sup> where the decomposition goes on in this gas layer and not upon the surface.

By performing experiments at low pressures, in which the molecules colliding with the filament possess on the average an energy corresponding to the temperature of the containing vessel such information may be obtained by varying the temperature of the reaction bulb, maintaining that of the filament constant. If the rate of reaction remains unchanged, it is certain that all molecules have an equal probability of reacting on the surface those of high energy content not being specially favoured. This would mean that the molecules which react sojourn on the surface at least long enough to come into complete thermal equilibrium with it. Langmuir<sup>9</sup> with this viewpoint in mind found that bulb temperature had no effect on the rate of attack of tungsten by oxygen to form  $WO_3$ . A similar test may be made with the tungsten-phosphorus system but with the important difference that the tungsten is not attacked.

### Anomalies in the Vapour Pressure of Red Phosphorus.

In dealing with the transformation red phosphorus  $\rightarrow$  white phosphorus, it has always been assumed that the vapour in equilibrium with both modifications consists of  $P_4$  molecules. If now the thermal relations concerning the reaction be examined a curious anomaly is revealed.

First it is necessary to collect the available somewhat scattered data on vapour pressures. From the experiments of Centnerswer and others<sup>10</sup> it is concluded that vapour pressure of liquid white phosphorus is given by

$$\log_{10} p \text{ (mm.)} = 9.6511 - 3297/T$$

which corresponds to a heat of evaporation of 15.8 kg. cal. per mole. Recalculating the data at 44–150° C., a smaller value of 12.9 kg. cal. is obtained. From the measurements of Smits and co-workers<sup>11</sup> on the variation of the vapour pressure of solid red phosphorus with temperature, the mean value obtained for the heat of evaporation is 25.6 kg. cal. The heat of transformation white to red is 4.0 kg. cal.<sup>12</sup> and if a small cycle be set up, it will be seen that there is a discrepancy in the heat content change of the system of 8.9 kg. cal. Admittedly the heat of transformation is not known very accurately, but it is certainly not in error by 8.9 kg. cal., which would be required to make good the discrepancy. Even such an approximate rule as that of Trouton shows that the vapour pressure of red phosphorus is anomalous. White phosphorus has a vapour pressure of 760 mm. at 280.5° C. and therefore Trouton's constant is 23. Red phosphorus has a vapour pressure of 760 mm. at 417.5° C., Trouton's constant being 37.4, compared with an average value of 22. If the hypothesis be made that red phosphorus is in equilibrium,

<sup>11</sup> Smits and co-workers, *Z. physik. Chem.*, 1914, **88**, 608; 1915, **90**, 129; 1916, **91**, 249.

<sup>12</sup> Giran, *Comp. Rendus*, 1903, **136**, 550, 677.

not with  $P_4$  molecules, but with  $P_2$  molecules, the anomaly may be removed to a large extent.

The cycle of processes is therefore amended to that shown

The energy of dissociation  $P_4 \rightarrow 2P_2$  has been taken as 30 kg. cal.<sup>13</sup> and hence the energy required to evaporate two moles of  $P_2$  is 46.9 or 23.9 cal. per mole. Other measurements have indicated the dissociation energy to be rather larger, namely 50 kg. cal. per mole,<sup>14</sup> from which the heat of evaporation turns out to be 33.5 kg. cal.

When red phosphorus is heated in an enclosure in order to determine its vapour pressure,  $P_2$  molecules evaporate and condense. In the gas they combine partly to form  $P_4$ , the equilibrium  $[P_2]^2 = K [P_4]$  being established. The measured vapour pressure is that due to  $P_4$  and  $P_2$  molecules and therefore is not a true indication since the equilibrium is almost wholly on the  $P_4$  side, at low temperatures. The observed vapour density in fact shows this to be the case and naturally it would be concluded that  $P_4$  molecules are in equilibrium with red phosphorus. The concentration of  $P_4$  molecules over red phosphorus is then given by

$$[P_4] = [P_2]^2 / K \cdot \exp. (-2\lambda_{P_2} / RT + E_{P_4 \rightarrow 2P_2} / RT) \sim e^{-\lambda_{R.P.} / RT},$$

where  $\lambda_{P_2}$  and  $\lambda_{R.P.}$  are the true and apparent heats of evaporation of the red modification. From the observed vapour pressures

$$E_{P_4 \rightarrow 2P_2} - 2\lambda_{P_2} = -25.8,$$

$$\text{therefore if } E_{P_4 \rightarrow 2P_2} \text{ is } 30.0, \quad \lambda_{P_2} = 27.9,$$

$$\text{and if } E_{P_4 \rightarrow 2P_2} \text{ is } 50.0, \quad \lambda_{P_2} = 37.9.$$

The first value is in good agreement with that calculated from the second cycle of processes. The second is definitely too high. The uncertain value of the energy of transformation may be the cause of the discrepancy—a higher value would be required to obtain better concordance. It so happens, if  $E_{P_4 \rightarrow 2P_2}$  is 30.0 kg. cal., the temperature coefficient of the pressure of  $P_4$  and  $P_2$  above red phosphorus gives an apparent heat of evaporation not far removed from the true value. The real vapour pressure will, however, be very much smaller than that observed.

If this argument be correct, it suggests a mechanism whereby  $P_4$  molecules may form red phosphorus and therefore how the transformation may proceed via the gas phase. The essential condition is that the phosphorus molecule— $P_4$ —be dissociated to  $P_2$  which must impinge on a surface before recombination in the gas can occur. Conversely, if red phosphorus be deposited as a result, say of the decomposition of phosphine, it would be inferred that  $P_2$  molecules were formed in the penultimate stage of the decomposition.

### Experimental.

The principle of the method employed in these experiments was simple. Phosphorus vapour from white phosphorus was admitted to a suitable

<sup>13</sup> Preuner and Brockmüller, *Z. physik. Chem.*, 1912, **81**, 129.

<sup>14</sup> Stock and Stamm, *Ber.*, 1913, **46**, 3497.

reaction bulb fitted with a tungsten filament and the 'clean up' followed by a Pirani gauge.

The white phosphorus was made in the following way. Red phosphorus was suspended in a hot solution of sodium hydroxide to free it from oxide. It was then washed, dried and sealed into the apparatus. It was at first heated gently in a good vacuum to remove all traces of water vapour and of oxide and then heated more strongly to obtain white phosphorus. The phosphorus reservoir was finally opened to the pumps for several hours and an appreciable fraction of white phosphorus evaporated in order to be absolutely certain that all traces of volatile oxides were removed. The vapour pressure was regulated by immersing the reservoir in a vacuum flask containing water or ice at the required temperature.

The Pirani gauge was fitted with a platinum filament 0.01 mm in diameter maintained at about 100° C., at which temperature the phosphorus vapour did not appear to attack the metal. The gauge was used by reading the voltage required to maintain the bridge circuit balanced, in which case the relationship

$$\frac{V^2}{1 + \frac{V^2}{V_0^2}} = kp$$

(where  $V_0$  and  $V$  are the balancing voltages for pressures zero and  $p$ ) holds valid up to pressures higher than those encountered in these experiments. Calibration was effected by immersing the phosphorus in a water bath at various temperatures and calculating the vapour pressures by extrapolation from measurements made at higher temperatures. This gave a value of  $k$  of 181, compared with 122 for oxygen, thus constituting an approximate test of the validity of the extrapolated values of the vapour pressure.

A number of different reaction vessels were employed, each being fitted with a divided filament for more accurate temperature determination, as has previously been described.<sup>6</sup> The method was however slightly altered. The two filaments were placed in one arm of the bridge and a high resistance voltmeter used for measuring the voltage drop across each filament. The total resistance of the two was known from the bridge resistances so the resistance of each could be calculated. A variable resistance could be inserted in place of the longer filament when measuring the contribution made by the shorter filament to the total reaction velocity. An accurate ammeter was also inserted in the bridge circuit so that the watts input to the filaments could be determined at any instant during the reaction. The filaments were thoroughly outgassed before use and the resistance temperature curve of the tungsten measured by separate experiments.

The reaction bulbs were cleaned with bromine water to remove red phosphorus, rinsed with distilled water and finally baked in vacuo at 350° C. for several hours. Temperature was controlled by immersion in a large vacuum flask containing water. Reaction vessel I (Fig. 2) was cylindrical, 2 cm. in diameter and had a volume including connections of 157 cc. Dimensions of filaments were 12 and 3 cm. long, 0.1 mm. in diameter. Reaction II was a bulb of about 5000 cc., fitted with short and thin filaments, the dimensions being so arranged that if every molecule striking the filaments reacts the half life is about 60 sec., if the reaction is unimolecular. By means of a ground joint and a small windlass a glass cylinder, 1 cm. in diameter, could be lowered to surround both filaments. In this way the red phosphorus could be collected before reaching the walls of the large bulb. Reaction vessel III was of similar external dimensions to I except that it was fitted with a single filament only. This was surrounded by a pyrex cylinder wound with nichrome strip which in turn was covered with another closely fitting cylinder. A Pt-Pt-Pd thermocouple in a thin pyrex sheath measured the temperature of the surface of the inner cylinder. The whole could be immersed in a bath of a CO<sub>2</sub>-ether mixture at -80° C. Reaction vessel IV consisted essentially of a plate P upon

which red phosphorus could be deposited by means of a moveable filament system not shown in the diagram. Above P there was a liquid air cooled surface L, and below a furnace F consisting of several spirals of tungsten backed by a nickel reflect or in order to heat P by radiation. Full details

FIG. 2.

of this tube will be published later. Reaction vessel V was again similar to I, but a single short filament was placed at the bottom of the tube; in some experiments to be described below a mica disc was suspended in the middle of the tube. Arrangements were also made for heating various parts of the tube by means of a moveable furnace.

### Results and Discussion.

A few typical runs with reaction vessel I (R.V. I.) showed that the phosphorus deposited readily as the red modification and approximately

From the dimensions of the apparatus, the fraction of molecules reacting to those striking the filament has been calculated, the assumption being made that every molecule activated by the filament is deposited

according to a unimolecular mechanism as may be seen from Fig. 3 where  $\log_{10} p_0/p$  is plotted against  $t$ .  $p_0$  is the initial pressure of  $P_4$  and  $p$  that after time  $t$ . Table I gives a series of runs carried out at different temperatures.

as the red modification and is not transformed back to  $P_4$  in the gas or at the walls. The temperature coefficient of this fraction yields an apparent energy of activation of 41 kg. cal. The red phosphorus was fairly uniformly deposited on the surface of the bulb but there was visible evidence that during some runs certain portions of the surface collected more red phosphorus than others. In addition, red phosphorus gradually made its way into other parts of the apparatus.

On account of the selective deposition of red phosphorus and also having re-

gard to the belief that the red modification is some kind of polymer, it appeared that the condition of the surface controlled the effectiveness of the encounters with the walls. In addition, the stream density of active molecules might also determine whether red phosphorus would be deposited at all. Some early preliminary experiments indicated that towards the end—90 per cent of  $P_4$  cleaned up—the reaction came to a stop, the pressure

phorus now being caught on the glass tube. Next the sheath was raised and a similar run carried out. The area upon which the deposit was now

of phosphorus remaining stationary. Upon increasing the temperature of the filament, deposition recommenced. To find whether the stream density did actually attain a critical value for phosphorus to be deposited, R.V. II. was employed in the following manner. By means of the windlass, the glass tube was lowered so as to surround both filaments and a clean up run made, the red phos-

being formed was  $1390 \text{ cm.}^2$  compared with  $15.7 \text{ cm.}^2$  or a  $10^2$ -fold increase. Four typical runs are quoted in Table II and it will be seen that the half life of the  $\text{P}_4$  molecules is not affected at all. It may be added that, after a number of runs had been carried out without the sheath, the surface of the large bulb was uniformly covered with red phosphorus. These experiments show conclusively that the stream density has nothing whatever to do with the probability of deposition and that the rate of "polymerisation" is likewise independent of the number of molecules striking the surface per  $\text{cm.}^2$  per sec.

**Calculation of the Theoretical Half Life.** As was stated above, R.V. II. was so dimensioned that if all the molecules striking the filament reacted, the half life would be conveniently measurable. From the Herz-Knudsen effusion equation the rate at which  $\text{P}_4$  molecules at  $15^\circ$  and at a pressure of 1 mm. strike the filament is  $1.85 \times 10^{20}$  per sec. per  $\text{cm.}^{20}$   $k$  the unimolecular velocity constant is defined by  $k = (-dp/p) dt$ . If  $A$  is the effective area \* in  $\text{cm.}^2$ ,  $n$  the number of molecules striking the filament per  $\text{cm.}^2$  per sec. at 1 mm.,  $V$  the volume of the reaction system in c.c. and  $N$  the number of molecules per c.c. at 1 mm. pressure at  $15^\circ \text{C.}$ , then

$$(-dp/p) dt = \frac{nA}{V \cdot N} \cdot k.$$

$$\text{But} \quad t_{\frac{1}{2}} = \ln 2 / k = \frac{N \cdot V}{n \cdot A} \ln 2,$$

which is 46 sec. for R.V. II.

The half life of phosphorus vapour in R.V. II. was then determined for a number of temperatures, and in the following Table III. the results

TABLE III.

	$t_{\frac{1}{2}}$ min.	Temp. $^\circ\text{C.}$	Efficiency $\epsilon$ .

	64.6	530	$1.38 \times 10^{-5}$

of a typical series of experiments are collected. For comparison a series obtained with R.V. I. are also included. When these are graphed by plotting  $\log_{10} \epsilon$  against  $1/T$ , it will be seen (Fig. 4) that at low efficiencies the line is nearly straight, the slope corresponding to an apparent energy of activation of 41 kg. cal., whereas as the efficiency rises the line curves round until it asymptotically approaches the value  $\log_{10} \epsilon = 0$ . The transition is gradual and shows no sign of any discontinuity. Since it is known that a clean tungsten surface may be obtained by heating to temperatures in the neighbourhood of  $2000^\circ$ , it is likely that at the lower temperatures employed, the molecules adsorbed on the surface are only those of phosphorus.

The fact that the observed and calculated half life periods agree so well in absolute magnitude leads to two important conclusions. The first is that all molecules which react on the filament condense as red phosphorus on the walls of the reaction vessel. Had, for example, an

\* For the purposes of calculation  $A$  is taken to be the geometrical area. Cf. J. A. Becker, *Reviews of Modern Physics*, 1935, 7, 103.

appreciable fraction reformed  $P_4$  molecules, the observed half life would not have approached the calculated value, but would have been much higher. On the other hand, if the evaporation of one active molecule had induced the reaction of several  $P_4$  molecules to yield a polymer by the successive addition of  $P_4$  units in the gas, the half life would have been smaller than theory predicts. This statement is also supported by the observation that surrounding the filament assembly with a sheath does not affect the reaction velocity, which might happen if a chain polymerisation had occurred with the eventual termination of the chains on the walls. It is a very remote possibility that the agreement is fortuitous, the two factors mentioned above exactly cancelling each other. What is also established from these observations is that the molecule, which ultimately forms red phosphorus, is not merely a  $P_4$  molecule which has come into thermal equilibrium with the surface of the filament and owes its activity to this alone. Otherwise the rate of deposition

FIG. 4.

would have increased on bringing a surface closer to the filament, for then there is less chance of the energy being dissipated by collisions with other molecules on diffusing to the walls.

### Energy Input to the Filament.

Since a considerable fraction of the molecules colliding with the filament at high temperature reacts, it became possible to measure approximately the energy required to activate a  $P_4$  molecule. During each run with R.V. II, the amperes flowing in the filament were observed and also the amperes required to maintain the filament at reaction temperature in vacuo. A typical run is recorded below (Table IV.).

The excess amperes are comparatively small, but the square of the excess is approximately proportional to the pressure of the phosphorus vapour, as is shown by the last column of Table IV. The total energy  $E$  supplied to the central part of the long filament in excess of that *in vacuo* and removed therefore by the  $P_4$  molecules is given by

$$E = R \int_0^{\infty} i^2 e^{-kt} dt.$$

(R is the resistance of the central part of the long filament.) But  $k$  the unimolecular constant is  $\ln 2/t_1$ , so integrating and substituting for  $k$

$$E = R i_0^2 \cdot t_1 \ln 2$$

where  $t_1$  is the half life due to the central portion of the long filament only, and  $i_0$  is the extrapolated value of the current at  $t = 0$ . This amounts to  $1.22 \times 10^{-1}$  cal. The number of moles deposited, that is, 5400 cc. of  $P_4$  at 0.015 mm. is  $7.9 \times 10^{-8}$ . The fraction of molecules reacting is 0.38. If the greater part of the energy supplied to the filament is employed in dissociating the  $P_4$  molecules, the energy of dissociation is  $1.21/4.8 \times 10^{-3}$  or 25.1 kg.cal per mole, which is in reasonable agreement with the value calculated from the variation of equilibrium constant with temperature. Two corrections, the magnitude of which it is difficult to estimate, must however be taken into consideration.

The temperature of the  $P_4$  molecule colliding with the filament is about  $15^\circ \text{C}$ ., whereas the temperature of the two  $P_2$  molecules leaving it is probably that of the filament. Secondly, the fraction (0.62) of the molecules which is not dissociated probably comes into thermal equilibrium with the filament thereby absorbing energy. The maximum amount removed in this way may be calculated as follows: The constant  $k$  of the equation relating voltage across the Pirani bridge with pressure is proportional to the accommodation coefficient of the gas on the filament and to the specific heat of the molecule at constant volume. Since no special precautions were taken to ensure a really clean surface of the Pirani gauge wire it is probable that the accommodation coefficients for oxygen and for phosphorus are nearly equal. In this case the ratio of the values of  $k$  then gives the ratio of the specific heats; that of  $O_2$  is 5.0 cal. per mole and therefore  $P_4$  is 7.4 cal./mole. The energy conducted away from the filament thus may become comparable with the heat of dissociation itself. The calculation of the dissociation energy is consequently subject to some uncertainty, but the figure obtained brings further support to the hypothesis that  $P_4$  molecules are activated by experiencing dissociation.

One possible mechanism of the dissociation can, however, at once be ruled out as a result of these experiments. If it were just a question of the  $P_4$  molecules being brought into thermal equilibrium with the surface, the "hot" molecules dissociating after leaving the filament, the fraction of molecules dissociated would be  $e^{-E/RT}$  where  $E$  is, at least, the energy of

dissociation of the  $P_4$  molecule and  $T$  is the absolute temperature of the filament. At  $1600^\circ$  this fraction is about  $3 \times 10^{-4}$  if  $E$  is  $30.0$  and  $3 \times 10^{-5}$  if  $E$  is  $50.0$ , compared with the observed value of  $0.38$ . The calculated fraction might be increased by supposing that more than two square terms contribute to the energy of activation, but the poisoning of the activity of the filament by oxygen, in addition to the evidence cited on page 276 indicates that the dissociation is a specific reaction rather than a mere heating of the molecules by transitory contact with the surface of the filament. The experiments with oxygen will be described elsewhere.

*The Evaporation of Red Phosphorus.* If  $P_2$  molecules always condense to red phosphorus, and that indeed is supported by all the evidence so far available, then when red phosphorus is heated it should give off only  $P_2$  molecules, provided the conditions are such that these may not combine to  $P_4$  before being detected. The evaporation must therefore be carried out *in vacuo* and at low evaporation rates.

A preliminary qualitative experiment to determine whether red phosphorus may be evaporated and again condensed as the red modification was made in the following way employing R.V. III. Phosphorus vapour was admitted and deposited as the red modification on the inner walls of the furnace by heating the filament. After thorough evacuation, the furnace temperature was raised to about  $400^\circ$ , the reaction bulb now being placed in a bath of  $CO_2$  and ether at  $-80^\circ$ . The temperature opposite the furnace was a little higher, namely,  $-50^\circ$ . The pumps were kept on during the evaporation of the phosphorus. Upon withdrawing the  $CO_2$  bath, the pressure on the vessel rose to about  $0.02$  mm. and when oxygen was admitted the characteristic glow of phosphorus was emitted. In another experiment the gas evolved could be redeposited as red phosphorus. During these experiments, however, red phosphorus was also deposited at the foot of the reaction vessel, on the coolest part. With this type of apparatus it is thus evident that both  $P_4$  and  $P_2$  molecules are obtained on heating red phosphorus. This does not mean that  $P_4$  molecules evaporate from red phosphorus, for the experimental conditions were such that it would not be impossible for the  $P_2$  molecules to recombine as will be seen from the following experiments made with R.V. I and R.V. V. On carrying out similar experiments with R.V. IV, in which the red phosphorus is slowly evaporated very nearly as a collision free stream of molecules directly on to a liquid air cooled glass surface, red phosphorus only is deposited.

#### Effect of Reaction Bulb Temperature on the Rate of Deposition.

In the introduction it was pointed out that if the energy of a molecule in the gas phase and its facility of reaction on a surface, there ought to be an increase in the velocity of reaction if the temperature of the containing vessel be raised. As the figures in Table V. demonstrate the phosphorus clean up exhibits just the opposite effect—the rate of reaction decreases. This at once precludes a test of the hypothesis, which however seems improbable from what was mentioned above in connection with the absolute rate of reaction and the temperature of the catalyst.

The increase in reaction bulb temperature introduces a complication unconnected with the mechanism of the reaction. The number of molecules colliding with the filament decreases in the ratio  $(T_P/T_R)^{1/2}$  where  $T_P$  and  $T_R$  is the temperature of the Pirani gauge and of the reaction vessel respectively. Since the pressure in the Pirani gauge is kept constant, the pressure in the reaction bulb will increase in the ratio  $(T_R/T_P)^{1/2}$ , for the mean free path is comparable with the diameter of the connecting tubes. These effects thus cancel. The total number of molecules in the system will have decreased by a factor  $(T_P/T_R)^{1/2}$ . If  $V_1$  be

the volume of the reaction system heated by the furnace and  $V_2$  that of connections and Pirani the number is reduced in the ratio  $(V_1 + V_2) \cdot \left( V_1 \sqrt{\frac{373}{288}} + V_2 \right)$  for the reaction vessel at  $100^\circ \text{C}$ . As  $V_1$  is comparable with  $V_2$  the correction only amounts to 5 per cent. and is neglected.

The following points, emerging from the results in Table V. are noteworthy. Although  $t_1$  increases with temperature, when the filament temperature is kept constant the value obtained with the reaction vessel at  $13.6^\circ$  can also be regained by heating the filament to a higher temperature. The phenomenon is reproducible, for in the last experiment at  $13.9^\circ$  the original low value of  $t_1$  is reached. These experiments could be repeated with a bulb carrying a heavy deposit or with a newly cleaned bulb. The red phosphorus deposited on the walls at low temperatures was not appreciably removed during a series of experiments involving heating the walls to  $200^\circ$ . On the other hand, if a clean tube were used to begin with, a visible deposit was not obtained opposite the filament as happens at room temperature when a similar amount of red phosphorus is deposited.

To obtain further information about the distribution of the deposit as well as the variation of  $t_1$  with temperature, a reaction tube similar to R.V. I. was fitted with a short filament near the bottom (R.V. V.). With this arrangement it was possible to study the distribution of the deposit as a function of the temperature of the reaction bulb.

The experiments with R.V. I. have shown that the absence of deposit opposite the filament when the reaction vessel is heated up is not due to the re-evaporation of red phosphorus to a cooler part of the reaction system, for if red phosphorus is deposited at room temperature and the tube heated to a higher temperature, there is no appreciable alteration in the distribution of the deposit. Presumably the  $\text{P}_2$  molecules may be reflected from a hot surface but, to explain the simultaneous increase in  $t_1$ , the  $\text{P}_2$ 's must partly recombine to form  $\text{P}_4$ 's, so that the gross efficiency of collisions with the filament is decreased. The probability of recombination also increases with rising temperature.

A further question arises with regard to the nature of the condensation. If the rate of deposition as red phosphorus is  $k_1[\text{P}_2]$  and that of recombination  $k_2[\text{P}_2]$ , both coefficients being temperature dependent in

opposite directions, than the ratio of the probability of depositing to combining is independent of  $[P_2]$  and also independent of the number of collisions the  $P_2$  molecule makes with the surface. If therefore a  $P_2$  molecule has to traverse a longer hot zone, repeatedly colliding with the walls of the tube, the value of  $t_4$  should be unchanged. This condition was simply obtained by moving the furnace further along R.V.V. from position 1 to position 2. The results are given in Table VI, while the distribution of the deposit after each set of experiments is indicated in Fig. 5. The temperature of the filament was maintained at a constant value throughout these experiments.

The results with R.V. 1. are confirmed by those with R.V. V. in so far as the increase in  $t_4$  is concerned, and from Fig. 5 it will be seen that

the red phosphorus is now deposited above the level of the furnace while the original deposit remains *in situ*. On raising the furnace to position 2, however, the value of  $t_4$  still further increases and now a third deposit is formed above the furnace. This means that the greater the distance the  $P_2$  molecules have to traverse the greater is the probability of their recombining

FIG. 5.

It is conceivable that the  $P_2$  molecules migrate along the surface of the glass to the cool part of the tube. To find whether this is the case, a mica disc was suspended about the middle of R.V. V. with a rectangular opening  $4 \times 7$  mm. in order to let the filament leads through. The edge of the disc only just touched the walls of the reaction vessel at a few isolated places. The disc was placed above the top of the furnace in position 1 so that if gas diffusion took place the disc would intercept the  $P_2$  molecules on their way to the cool surface. Upon examining the disc after carrying

out an experiment it was found to be covered with a uniform red deposit which obviously had not migrated from the points of contacts of the disc with the walls. The conclusion is, therefore, that the  $P_2$  molecules diffuse through the gas, being reflected at the walls of the reaction tube.

Owing to its position the disc was at some temperature between  $15^\circ$

TABLE VII.—MICA DISC IN R.V. V.

Initial Pressure mm.	$t_4$ min.	Temp. of R.V.	Position of Furnace.
0.0102	1.8	13.9	—
0.0183	5.6	79	1
0.0191	7.5	79	2
0.0178	2.1	14.4	—

and  $80^\circ$ . A fraction of the impinging molecules would combine; the remainder would be deposited. The interposition of the disc ought to increase  $t_1$  not only in position 1 but also in position 2, since the  $P_4$  molecules now escape through the rectangular aperture ( $0.28 \text{ cm.}^2$ ) which is small compared with the cross-sectional area ( $3.1 \text{ cm.}^2$ ) of the reaction tube. The results in Table VII. are in accordance with expectation, the increase in position 1 and 2 being relatively much greater when the disc is interposed than when it is absent.

These results are to be compared with those in Table VI. The disc naturally does not affect  $t_2$  when the reaction bulb is at room temperature. A decision now has to be made about the mode of recombination of  $P_2$  molecules. If they combine in the gas, it is unlikely that a three body collision is necessary for this purpose. The time required for a  $P_2$  molecule to reach the surface of R.V. I. is  $10^{-4}$  sec. The rate at which  $P_2$  molecules are produced is of the order of  $10^{-4} \text{ mm./sec.}$ , and so the stationary concentration is  $10^{-8} \text{ mm.}$  In  $10^{-4}$  sec. one  $P_2$  molecule would make  $10^{-5}$  collisions with other  $P_2$  molecules on diffusing to the walls and therefore gas phase recombination may be neglected in this vessel. Even in R.V. V. where diffusion occurs over a maximum distance of 15 cm., the probability of two  $P_2$ 's colliding is about equal to that of reaching the cool surface. It would seem, therefore, when the temperature of the walls is raised, a decreasing fraction of the molecules form red phosphorus, the remainder diffuse to the cool surface but in so doing a fraction recombine on the walls. At higher temperatures  $P_2$  molecules must again remain unassociated, for it has been shown that  $P_4$  molecules on passing through a hot silica jet are dissociated to  $P_2$ . Moreover this is a necessary consequence of the theory that  $P_2$  molecules are in equilibrium with red phosphorus and therefore condense as such on colliding with red phosphorus.

### Conclusion.

All the evidence presented in the preceding pages points to the conclusion that  $P_2$  molecules condense to red phosphorus and conversely red phosphorus evaporates in units of  $P_2$ . The vapour pressure anomalies are removed if the assumption be made that  $P_2$  molecules are in equilibrium with red phosphorus. There is therefore no more justification for regarding red phosphorus as a polymer than in supposing, for example, solid chlorine is a polymer made up of  $Cl_2$  molecules. The structure of red phosphorus must simply be such that, energetically,  $P_2$  molecules preferentially evaporate, whereas the white modification would appear to possess aggregates of four phosphorus atoms which are most easily detached as a whole from the solid or liquid surface. Unfortunately there are no X-ray data to give any guidance on this point.

It would therefore be more correct to term the transformation white to red phosphorus a depolymerisation reaction.

### Summary.

Attention is called to certain discrepancies regarding the vapour pressures of white and of red phosphorus if, as is usually supposed,  $P_4$  molecules are considered to be in equilibrium with both modifications. The discrepancy can be removed if the assumption is made that  $P_2$  molecules are in true equilibrium with red phosphorus.

Experimental evidence is adduced in support of this hypothesis. First it is shown that  $P_4$  molecules, on being dissociated to  $P_2$ , by passing through a hot silica jet, condense to red phosphorus on striking a glass surface.

$P_4$  molecules may also be dissociated on a tungsten surface. The kinetics of this reaction have been studied in some detail with these results. The reaction is unimolecular and possesses an energy of activation of 41 kg.cal. at low filament collision efficiencies. By using a large bulb and a small filament it is shown that every  $P_4$  molecule dissociated forms red phosphorus, the probability of deposition being independent of stream density over a 200-fold range. It is further shown that  $P_2$  molecules are reflected from glass surfaces at temperatures greater than 15° C. and tend to diffuse to a cool surface if this is possible. In the temperature range 15–200°,  $P_2$  molecules may be made to combine on a glass surface.

Red phosphorus can be sublimed to red phosphorus only, if sublimation is carried out under proper conditions.

These observations are discussed in relation to the theory that red phosphorus is a polymer of white phosphorus. It is concluded that in reality it would be more accurate to consider red phosphorus as a depolymer.

The authors wish to thank Prof. E. K. Rideal and Dr. E. B. Ludlam for their advice and encouragement during this work. One of them (H. W. M.) is indebted to the Loyal Commissioners for the Exhibition of 1851 for a Senior Studentship. The other thanks the Trustees of the Moray Fund of the University of Edinburgh for a grant.

### GENERAL DISCUSSION.

**Dr. R. G. W. Norrish** (*Cambridge*) said: It seems to me that the authors go too far in their contention that red phosphorus is not a polymer in the true sense of the word. They state at the end of their paper that there is "no more justification for regarding red phosphorus as a polymer than in supposing, for example, solid chlorine is a polymer made up of  $Cl_2$  molecules." This surely cannot be admitted; the liquefaction and solidification of a volatile substance like chlorine takes place through the operation van der Waals' forces, and gives rise to a solid of low melting-point which is in no sense a polymer.

The condensation of  $P_2$  to red phosphorus, on the other hand, yields a solid of very high melting-point (ca 630° C.) in which primary valencies must be involved; this is essentially a true polymerisation. The correct conclusion from Melville and Gray's results would seem to be that while  $P_2$  is the "monomer" red phosphorus is the "polymer." The pressure of  $P_2$  gas existing in equilibrium with red phosphorus is then more properly termed a dissociation pressure, rather than a vapour pressure.

We have an exactly similar phenomenon in the dipolymerisation of polyoxy-methylenes. Our own work as described in our paper, and also the results of Spence, show that between 70° and 100° C., there is a very large pressure of monomeric formaldehyde in equilibrium with the solid. This does not mean that the solid is not a polymer, but only that the chemical reaction of polymerisation is reversible for there can be no doubt from the work of Staudinger that primary valencies are involved.

**Dr. H. W. Melville** (*Cambridge*) said, in reply to a question by Professor Travers: That hydrogen and acetylene are primary products of the dissociation of ethylene has been shown by chemical analysis of the gas (see references in the introduction to the paper) in addition to the evidence from pressure measurements alone.

*In reply to Dr. Norrish:* While admitting that the analogy between chlorine and phosphorus is not perhaps the best that could be given, yet in the stricter sense red phosphorus could not be termed a polymer. As is evident from the present discussion, the definition of a polymer is, however, a very wide one, and therefore taking into consideration Dr. Norrish's demonstration of the reversible depolymerisation of acetaldehyde and formaldehyde, it would not be incorrect to call red phosphorus a polymer. But the structure based on X-ray analysis<sup>15</sup> does not show any evidence of the existence of aggregates of more than four P atoms separated from each other by considerable distances, such as were previously imagined to occur in red phosphorus.

## ON THE KINETICS OF THE POLYMERISATION OF 1·3 BUTADIENE IN THE PRESENCE OF METALLIC SODIUM.

BY A. ABKIN AND S. MEDVEDEV.

The many-sided study of polymerisation processes, as a result of which a polymolecular substance, in some cases similar to rubber, develops, offers vast theoretical and applied interest. Kinetic investigations must obviously play a rôle in this study. Apart from the fact that the settlement of the problems of the mechanism of polymerisation processes can be arrived at only on the basis of kinetic research, even a general investigation from the point of view of formal kinetics and the determination of the peculiarities of the phenomena of these singular processes may yield extremely interesting results.

Some interest in the kinetics of polymerisation processes arose following the successful development and the application of the concept of chain reactions to it.<sup>1</sup> Indeed many observations—sensitivity to light, influence of inhibitors, the frequently observed connection between oxidation and polymerisation, the wall effect—speak in favour of the chain mechanism. It is quite natural, however, that in this work on the initiation and development of the chain theory, the specific processes of the polymerisation reaction were not cleared up for a long time.

In polymerisation reactions, which frequently occur in the liquid phase with a gradual increase in viscosity, molecules take part which grow in size during the process reaching exceedingly large proportions. This must apparently have its reflection in general and molecular kinetics.

The aim of this work is to clear up the kinetic regularities in the polymerisation of 1·3 butadiene in the presence of metallic sodium. This reaction, in comparison with others, has the advantage that it has been investigated in detail by Ziegler<sup>2</sup> and his co-workers, who gave an extremely graphic and plausible plan of the action of sodium and the

<sup>2</sup> Ziegler and Bähr, *Ber.*, 1928, **71**, 253; Ziegler, Crössman, Cleiner, and Schäfer, *Ann.*, **473**, 1; Ziegler and Cleiner, *Ann.*, **473**, 57; Ziegler, Dersch, and Wollthan, *Ann.*, 1934, **511**, 13; Ziegler, Jakob, Wollthan and Nenz, *Ann.*, 1934, **511**, 64.

other alkali metals. Moreover, a study of this reaction has also a practical interest, in view of its use in the process of the production of synthetic rubber.

In the preliminary investigations it was shown that polymerisation is extremely sensitive to oxygen, which, together with its sensitivity to light, determined the experimental conditions. The study of the polymerisation of butadiene was carried out in both the liquid and gaseous phases. Since the experimental figures and the results will be dealt with later, it is necessary in the first place briefly to note the fundamental points in the performance of the experiments and to describe the method of investigation.<sup>3</sup>

### Apparatus and Methods.

The butadiene was obtained from the pure tetrabromide (m.p. =  $117^{\circ}\text{C}$ .), which was recrystallised not less than five times from alcohol. The reaction took place in an apparatus which permitted the collection

*Apparatus for the study of polymerization in the gaseous phase*

FIG. 1.

of the butadiene in an atmosphere of nitrogen, carefully freed from oxygen. In this, butadiene was subjected to many fractionations and was collected in ampules, from which it was transferred when needed to the apparatus for the investigation of polymerisation. The latter consisted of a thick walled glass vessel (Duran) joined to a metallic valve of a special construction, which rendered the apparatus hermetically sealed under increased pressure and under vacuum. For each experiment 2 c.c. of liquid butadiene were introduced into the vessel. All the operations from the collection of butadiene to the completion of polymerisation were carried out in the complete absence of oxygen. Metallic sodium (25-40 mg.) in the form of wires 0.4 mm. in diameter was introduced in a current of pure nitrogen. Polymerisation took place in a thermostat ( $+0.025^{\circ}\text{C}$ ). In each experiment the amount of sodium and butadiene, the amount of polymer obtained in time  $t$ , and the quantity of unchanged butadiene were determined. Repeated experiments in which we used butadiene prepared at one and the same time were fully satisfactory, differing by no more than 3 per cent. of the weight of the initial butadiene.

<sup>3</sup> A detailed description of the apparatus, methods, and experimental data will be published in the *Acta physicochem.*, U.S.S.R.

In the course of the work it was observed that the gaseous butadiene also polymerises in the presence of metallic sodium. For the study of this extremely singular reaction a special apparatus was constructed, shown in Fig. 1. The set-up for the gaseous polymerisation was so constructed that the process of polymerisation could be observed either volumetrically (under constant pressure) or manometrically (under constant volume). The first method has the advantage that the constant is obtained by direct measurements and therefore, for comparative measurements, it is more convenient than the manometric method.

The reaction vessel in this case was of the form of a Dewar vessel, upon the inner surface of which (on cooling with solid  $\text{CO}_2$ ) a layer of metallic sodium of the desired thickness was deposited by sublimation from the ampules, which were then unsoldered. In order to duplicate results it is necessary that the entire system be completely washed with pure nitrogen and, so far as possible, completely evacuated. It was also necessary completely to remove mercury vapour and inactivated sodium by means of tubes containing gilded asbestos soldered between the reaction vessel and the whole apparatus containing mercury.

The reaction vessel is connected with a system of manometers, burettes, pressure regulators, and other devices ensuring complete and necessary accuracy of measurement. Butadiene was introduced into the system from an ampule opened electromagnetically. A burette containing oxygen was also included in the system for the study of the effect of oxygen on the polymerisation or, in special cases, for its complete poisoning.

Repetition of results on the same layer was quite satisfactory. On different layers it was not possible to obtain fully concordant results, which is quite understandable, since the rate of polymerisation depends to a great extent upon the dispersion and thickness of the sodium layer, the size of its surface, and the volume of the vessel, and on other factors the conservation of the constancy of which in different experiments is extremely difficult. For this reason all comparative measurements were made on one and the same layer of sodium.

### General Description of the Rate of the Process.

In the case of technical butadiene (79 per cent. butadiene, 19.5 per cent. pseudo-butylene, and some 0.01 per cent. aldehyde) as was expected,

Figure 2

the experiments gave poor results. The induction period varied between 20 and 100 hours. The stages of noticeable polymerisation varied in different experiments in the same way. The absence of reproducibility was connected not so much with the presence of a large amount of pseudobutylene, which has very little noticeable effect, as with the presence of a small sometimes analytically undeterminable quantity of other substances, especially aldehyde.

Identical results were obtained only when carefully purified butadiene was used and when the experiments were performed in the absence of oxygen and light. No induction period as such was observed in this case. The process from the start occurred with increasing rapidity

and on the expiry of several periods became stationary. The form of the curve (see Fig. 2), per cent. polymerisation  $t$ , resembles the analogous curve for "branched chain" reactions ("degenerated explosions"). This resemblance is, however, only external. Actually in cases of energetic or material chains the carriers of which are comparatively unstable compounds of the type of free radicals, following the interruption of the process (*i.e.*, rapid cooling) and its subsequent renewal, results should have been obtained which do not fit into the frame of kinetic continuity. On cooling the reaction system with liquid air the results were fully identical with those received for the same period without interruption. The same is observed, but still more clearly, in the process of polymerisation in the gaseous phase and is a convincing proof of the absence of chains in the given reaction.

In connection with Ziegler's<sup>2</sup> extremely plausible assumption that the polymerisation of diene hydrocarbons in the presence of the alkali metals proceeds through metal-diene conjugate links, and in connection with the assumptions of several investigators as to the homogeneity of the process studied,<sup>4</sup> we carried out experiments in the vessels shown in Fig. 3.

In vessel 1 the reaction first took place in bend *a*. After the degree of polymerisation reached a definite stage, the liquid was poured into *b* by inclining the apparatus. An extremely interesting phenomenon was then noted: polymerisation still takes place in *a*, and after some time the liquid in *b* completely disappears. The rate of this gaseous

polymerisation corresponds to the rate of the polymerisation in the liquid phase, *i.e.* under identical pressures the rates of the liquid and gaseous phase polymerisation are the same.

These experiments, however, do not exclude the possibility of a homogeneous process, since its rate, which is determined by the concentration of the sodium-butadiene compounds, must be small in comparison with that of the process occurring in the presence of sodium where, consequently, the development of new sodium-butadiene molecules continually occurs.

The absence of a homogeneous process, however, is readily shown by the experiments in vessels 2 and 3. The second vessel is bent in such a manner that, after pouring the liquid from *a* into *b*, it is possible to pour mercury contained in *c* into *a*, thus covering the sodium polymer with mercury and removing the possibility of gaseous polymerisation. The experiments in vessel 3 differed from those in vessel 2 only in the fact that, after the pouring, the bend *a* with the sodium and the polymer was

FIG. 3.

<sup>4</sup> Zelmanov and Shalnikov, *J. Physic. Chem. (U.S.S.R.)*, 1933, 3, 353.

unsoldered, and thus the possibility of poisoning the homogeneous process with mercury vapour was stopped. The experiments in vessels 2 and 3 showed that the poured liquid, even after standing for many months, did not polymerise. We thus ascertained the heterogeneous character of the polymerisation of butadiene in the presence of sodium.

During the investigations of the liquid phase polymerisation, we discovered the poisonous effect of oxygen, which is easily explained by the destruction of the sodium-butadiene compounds by oxygen. This

phenomenon is, apparently, extremely typical for the polymerisation of diene hydrocarbons under the influence of the alkali metals. In other cases, especially where as a basis of polymerisation there is a clearly defined chain mechanism as, for example, during the autopolymerisation of chloroprene,<sup>6</sup> oxygen is a positive factor in the rate of the process.

It has already been noted above that, under identical pressures, kinetic polymerisation is absolutely identical for both the liquid and gaseous phases.

The same peculiarities are therefore observed in the gaseous phase polymerisation, but in a more pronounced form. Furthermore, the results obtained during the study of the gaseous phase polymerisation make it possible to give a more detailed description of the kinetic process.

Just as in the case of polymerisation in the liquid phase, an interruption of the gaseous phase reaction (in this case it is more convenient not to cool but to pump butadiene out of the reaction vessel) does not disturb the normal course of the process.

Fig. 4 shows a typical polymerisation curve on a thin layer of sodium under

Figure 4 Polymerization in the gaseous phase

constant pressure ( $p = 742$  mm.), and at  $30^\circ$  C. At the marked points butadiene was pumped out and then re-introduced into the system. It is noteworthy that after evacuation the previous rate is resumed only after some time since, after the introduction of butadiene into the evacuated vessel, there is always an increase in the rate due to the solution of the monomer in the polymer (in Fig. 4 this time is excluded). We see here also

<sup>6</sup> This was noted by Williams and Walker, *Ind. and Eng. Chem.*, 1933, **25**, 199. (The effect of oxygen on the polymerisation of chloroprene is being studied in detail in our laboratory.)

the entire initial non-stationary period, consisting in a gradual development of the primary sodium-butadiene compounds, while all the sodium in the layer has not completely reacted.

Fig. 5 records one of the experiments illustrating the effect of oxygen. Curve 1 shows the rate of reaction prior to, and curve 2 after the addition of oxygen. These experiments were performed with a thick layer of the polymer and therefore the superimposed effects of solution are extremely large. Upon a considerable period of contact between the oxygen and the sodium-butadiene polymer, polymerisation ceases entirely. An actual difference is noted between polymerisation upon a thick and a thin layer of sodium. The difference consists in the fact that with a thick layer of catalyst in the system, there is always present metallic sodium to which the butadiene diffuses, developing new sodium-butadiene centres. This factor increases the rate

Figure 5

On the other hand the increase of thickness of the layer of the polymer serves as a gradually growing obstacle to the passage of butadiene to the sodium. Moreover, with thick layers, upon a rapid pumping out of the system the polymer peels off and a new surface of sodium is formed causing an increase in the rate. As a result of this, less clear-cut results are obtained. Systematic experiments with polymerisation in the gaseous phase were, therefore, carried out upon thin layers of sodium. In these cases, after several periods of increase in rate, a completely stationary reaction begins.

### The Mechanism and Kinetics of Polymerisation.

Ziegler's data and our results point to the following general plan of the mechanism of the polymerisation of butadiene in the presence of sodium. Butadiene reacts with sodium developing primary bi-sodium compounds (reaction A). The reaction of polymerisation consists in the successive additions of butadiene molecules to these compounds (reaction B).

If the butadiene reacts with the sodium-organic compounds at its 1 and 4 carbon atoms, then the process of polymerisation can be conceived as a successive inclusion of butadiene molecules between the carbon and the sodium of the sodium-organic compound. Thus, sodium keeps

on shifting to the peripheral regions and is concentrated on the surface of the polymer where it reacts with the primarily adsorbed butadiene, a fact that might have explained the heterogeneous character of polymerisation. This general scheme, except for the surface nature of the process, as will be shown later, is proved by the kinetics of the process. The formal resemblance to, and the difference from chain kinetics, consists in that in this case the "active centres" are themselves products of the reaction: sodium-butadiene compounds, always capable of reacting with new molecules of butadiene. As Ziegler proposes and our experiments confirm, the rate of formation of the primary sodium-butadiene compounds is significantly less rapid than the rate of the subsequent additions of butadiene to the sodium-organic compounds. Thus the

appearance in a unit of time of a small number of primary centres aids the reaction of a large number of butadiene molecules. While, therefore, metallic sodium is present in the system, a non-stationary period is observed analogous to the phenomenon of "degenerated explosions," where the branching of the chains is accomplished as a result of a slowly occurring parallel or successive reaction. In this case such a parallel reaction, leading to the development of a new "active centre," is the reaction between butadiene and metallic sodium. The question as to whether or not the reaction takes place on the surface of, or within, the polymer was decided by a study of the kinetics of the reaction.

Experiments with the thick coating of sodium have already shown that, in the case of a thin layer of the polymer, diffusion of butadiene

to sodium occurs, resulting in an additional rate which is very large in comparison with the initial rate. It was further ascertained that the rate of the process depends very closely upon the square of the pressure. In Fig. 6 (where a pressure-time curve is recorded, calculated according to the bimolecular law, with the constant equal to  $1.05 \times 10^{-6}$  (mm. Hg, min.)) it is seen that the experimental points coincide very closely with the calculated curve. These facts do not well accord with the conception of the surface nature of the process.

The strict treatment of the reaction occurring within the polymer cannot at present be worked out, owing to the absence of necessary data (coefficient of diffusion, internal friction, etc.).

However, some of our data allow a general interpretation of the process of polymerisation as a reaction occurring within the polymer. A study of the phenomena of solution in the layer of the polymer, in which the sodium-organic compounds were previously broken by the action of oxygen, showed that the initial rate of solution is more than twice the rate of reaction. In this case it is possible that the concentration of butadiene in the polymer is determined by a condition of equilibrium:

$$\frac{C_{\text{gas}}}{C_{\text{polymer}}^n} = \text{Constant} \quad (1)$$

and during the process keeps at a constant, or nearly constant, level. The concentration and distribution of sodium within the polymer is another kinetic factor. We can infer from the constancy of the rate only that there is a constant number of sodium atoms. It is quite possible, however, that the butadiene molecules combined with the sodium-organic compounds both by their 1 and 4, as well as by their 1 and 2 carbon atoms. The absence of thread-like crystals in drawn-out butadiene rubber also speaks in favour of an interlaced net structure. The conception of a more or less equal distribution of sodium atoms within the polymer must, therefore, be considered as extremely likely, and, as an average value for its concentration, that obtained from analysis can be adopted. If we take into consideration that the coefficient of distribution

$$\alpha = \frac{p}{C^n},$$

then the dependence on the rate of polymerisation which we measure by a manometer is determined by the equation:

$$-\frac{dp}{dt} = \frac{K}{\alpha^{1/n}} p^{1/n} \quad (2)$$

We must not lose sight of the fact that the constant concentration of sodium also enters into the rate coefficient. For a correspondence of equation (2) with the bimolecular law upon which the reaction depends, it is necessary that  $n = \frac{1}{2}$ . As is seen from Table I., where our experimental results are recorded, this requirement is fulfilled extremely satisfactorily.

TABLE I.—THE DISTRIBUTION OF BUTADIENE BETWEEN THE GASEOUS PHASE AND POLYMER.  $t = 30^\circ \text{C}$ .

$p_{\text{mm.}}$	Amount in c.c. of Absorbed Butadiene in 1 c.c. of the Polymer.	$\frac{C_{\text{gas}}}{\sqrt{C_{\text{polymer}}}} \times 10^2$
636	17.92	3.81
375	6.80	3.05
293	4.32	3.58

The determination of the energy of activation (for the calculation of which, however, it is necessary to consider the temperature dependence of the coefficient of distribution) is of great interest. If the observed rate of the disappearance of butadiene as a result of the reaction is

$$w = Ka,$$

where  $a$  is the concentration or its proportional quantity (c.c. of butadiene in 1 c.c. of the polymer), then the dependence of the true rate of reaction on the temperature can be represented by a change of this relation :

$$K = W/a.$$

In Table II. are recorded the experimental results of these determinations, made under constant pressure ( $p = 355$  mm.).  $E$  is the energy of activation determined from the calculation of the distribution.

TABLE II.

$t^{\circ}\text{C.}$	$w$ (c.c. 15 min.)	$a$ (c.c. of Butadiene in 1 c.c. of Polymer.)	$K = w/a$	$E_{\text{cal.}}$
30	2·6	11·2	0·2317	7400 7185
40	3·2	9·3	0·3441	
50	3·4	6·9	0·4921	

Neglecting the fact that, in the observed rates ( $w$  at  $40^{\circ}$  and  $50^{\circ}$  C.), the difference is extremely small and close to experimental error, the calculation of the value of the energy

of activation leads to a surprising coincidence. The value obtained for the energy of activation is considerably lower than that for a normal molecular reaction. It lies between those limits within which are found a value for the energy of activation between radicals. To conclude from this, however, that a reaction also occurs here with free radicals, is, of course, not permitted; but it points indirectly to the possibility of some preliminary activating processes which the butadiene undergoes upon solution in the polymer. The more so, that the idea of the relationship

$$\frac{C_{\text{gas}}}{\sqrt{C_{\text{polymer}}}} = \text{Constant}$$

consists in that butadiene in the polymer behaves osmotically as a dimer. If polymerisation occurs within the polymer, then for a characteristic rate of the process it is necessary to determine the rate constant of this reaction ( $K_2$ ). Its rate is expressed by the equation

$$-\frac{d(\text{Bu})}{dt} = K_2(\text{Bu})(\text{Na}) \quad . \quad . \quad . \quad (3)$$

where (Bu) and (Na) are the concentrations of butadiene and sodium within the polymer.

For the calculation of  $K_2$  we can use the data recorded in Fig. 6. The rate constant in this case equals  $1·05 \times 10^{-6}$  mm./min., the volume of the system = 328 c.c., and the volume of the polymer = 1·14 c.c. Neglecting the amount of polymer during the experiment and consequently considering the concentration of sodium as constantly equal

to  $5 \times 10^{-3}$  mole/litre (from an analysis at the end of the experiment), we get

$$K_2 = 2.5 \times 10^{-2} \text{ mole/litre.}$$

On the basis of the value found for the energy of activation, *i.e.* 7300 cal., we find

$$K_2 = 4.7 \times 10^3 \times e^{-\frac{7300}{RT}}.$$

For the pre-exponential member we get an extremely small value, depending on the specificity of the media in which the reaction occurs.

### Summary.

(1) The polymerisation of butadiene under the influence of metallic sodium was studied in the liquid and gaseous phases. The rate of the process was examined in the case of carefully purified butadiene in the absence of oxygen.

(2) It is shown that polymerisation in the liquid phase occurs heterogeneously. The rates of the gaseous and liquid phase processes are the same if polymerisation is in both cases performed under identical pressures.

(3) Independent of whether the polymerisation is performed in the gaseous or liquid phases a period is always noted at the beginning where the rate increases to a definite value, after reaching which it becomes constant. This non-stationary period is connected with the development of primary sodium-butadiene compounds, and lasts so long as metallic sodium remains in the system. The rate of this primary reaction bears only a small relation to the rate of the subsequent combinations of the butadiene with the sodium-organic compounds, later developing the final molecule of the polymer. In consequence, an external resemblance to chain kinetics is observed in the kinetics of the polymerisation of butadiene.

(4) The strong inhibiting (poisonous) effect of oxygen on the process of the polymerisation of butadiene under the influence of metallic sodium, is shown, which fully agrees with the conception of the rôle of the sodium-butadiene compound in the process studied.

(5) The primary conception of the polymerisation as a surface process does not correspond to experimental results. An assumption is made that the process of polymerisation consists in the successive addition of butadiene molecules to sodium-organic compounds, occurring within the polymer itself. It is further shown that this assumption fully agrees with experimental results obtained in the study of the process.

(6) The rate constant of the process taking place within the polymer is determined as well as its energy of activation, together with its pre-exponential member.

### GENERAL DISCUSSION.

Dr. E. Bergmann (*Rehoboth*) said: Whilst during this discussion the suggestion has been stressed several times that polymerisation is a chain reaction, the mechanism proposed by the Russian authors for the dimethyl-butadiene polymerisation with metallic sodium leads to a stepwise reaction, and not to a chain. Since it is rather doubtful whether a step-reaction will account for the characteristics of a polymerisation, the following mechanism is proposed. One molecule of the diene adds *one* atom of sodium:

and gives under displacement of the double bonds a free radical. Since the latter can combine with a new diene molecule by way of a transfer of the free valency

and so on, the above radical can be a carrier of a chain. The sodium-reaction, therefore, is a real chain reaction. The suggestion made is so much the more probable, as in the laboratory of Professor Schlenk several cases have been observed where the addition of sodium metal to ethylene compounds results in the first step in the formation of a radical, *e.g.*,

which may stabilise by dimerisation or any other reaction.

*The author's reply appears at the end of this number.*

## THE MOLECULAR WEIGHT OF POLYSTYRENES AND THE SHAPE OF THE MOLECULES IN SOLUTIONS.

BY R. SIGNER, *Bern.*

*Received 7th August, 1935.*

We shall give a summary of experiments on the double refraction of flow of polystyrene solutions and on their behaviour in Svedberg'-ultracentrifuge.<sup>1</sup> Both phenomena—the mechanically induced anisotropy of colloidal solutions, and their sedimentation in a strong centrifugal field—are dependent upon the size and shape of the colloidal particles. Our experiments are therefore likely to bring fresh material to the as yet unexhausted discussion of the structure of colloidal solutions.<sup>2</sup>

### Direct Determination of Molecular Weight by the Ultracentrifuge.

Like all colloidal dispersions, the solutions of polystyrenes show the phenomenon of a sedimentation equilibrium in a centrifugal field. The

<sup>1</sup> Detailed publications as to the double-refraction of flow of the polystyrenes will be found in the *Z. physik. Chemie*, **A**, 1930, **130**, 257, and 1933, **165**, 161. The ultracentrifugation of polystyrenes has been fully described in *Helv. Chim. Acta*, 1934, **17**, 59, 335 and 726. The measurements have been carried out at the university laboratories of physical chemistry at Upsala, Sweden.

<sup>2</sup> The actual state of the problem of the size and form of polystyrene-molecules is as follows: H. Staudinger uses viscosity data obtained with dilute solutions to determine the length of the molecules and defends the assumption that they are straight rods; *cf.* his book *Die hochmolekularen organischen Verbindungen*, Berlin, 1932. The exactness of the viscosity method of determining molecular weights is doubted by other investigators. They imagine the most probable molecular form to be that of thread balls or clusters—see *e.g.*, W. Kuhn, *Kolloid Z.*, 1934, **68**, 2; further, E. Guth and H. Mark, *Monatshefte für Chemie*, 1935, **65**, 93.

distribution of the dissolved material in the equilibrium state permits the determination of the osmotic effects of the dissolved particles. Vant Hoff's relation between osmotic pressure and molecular weight leads to the calculation of an "apparent" molecular weight. General experience shows that, with solutions of long thread molecules the "apparent" and true chemical molecular weights are identical only in dilute solutions. At higher concentrations the apparent molecular weights turn out to be much smaller than the true ones.<sup>3</sup> With increasing size of the molecules, the region of concentrations in which the determination of the molecular weights from osmotic pressure remains admissible becomes smaller and smaller.<sup>4</sup>

The ultra-centrifuge permits the determination of the osmotic effects at very small concentrations. Solutions, whose osmotic pressure does not exceed 0.01 mm. of mercury, already show a correct equilibrium-distribution in the centrifugal field, undisturbed by any secondary effects. The ultracentrifuge can therefore be used for investigations of much more highly diluted solutions than the ordinary osmometer. The molecular weights of very high molecular polystyrenes can be determined directly, without recourse to an unsafe extrapolation of the osmotic pressure towards infinite dilution.

Table I. contains the results of the ultra-centrifugal determination of molecular weights of three polystyrene-fractions. The first column

The molecular weights of the three

polystyrene fractions are to the first approximation, proportional to their specific viscosities. The measurements thus confirm, for high-polymers, a law formulated by Staudinger for low molecular substances. Hydrodynamics requires that the specific viscosity of a solution of rod-shaped molecules should increase roughly with the square of the molecular weight.<sup>5</sup> If the values of the molecular weights, given in Table I.,

<sup>3</sup> From the more recent experiments we may quote those by K. H. Meyer and R. Lühdemann, *Helv. Chimica Acta*, 1935, 18, 307.

<sup>4</sup> See *Helv. Chim. Acta*, 1935, 18, 701.

<sup>5</sup> The possible error is so wide because of the poly-dispersity of the fractions and the necessity of using an approximation method for the calculation of the mean molecular weights, see *Helv. Chim. Acta*, 1934, 17, 335.

<sup>6</sup> See e.g., W. Kuhn, *Kolloid Z.*, 1934, 68, 2.

obtained by the ultra-centrifuge, are to be trusted, then either the molecules of the polystyrenes are far from being straight rods, or the laws of hydrodynamics are no more valid in the case of very thin threads. In the next sections we shall describe experiments which prove the unsatisfactory character of the usual hydrodynamic treatment, and make it probable that the polystyrene molecules in fact are more or less linear.

### The Velocity of Sedimentation.

With centrifugal fields of the order of about  $10^5$  times the gravitation constant, the velocity of sedimentation of polystyrene solutions can be studied over a wide interval of concentrations. A safe extrapolation gives the sedimentation velocity for an infinitely small concentration, *i.e.*, for a state in which the molecules move freely in the solvent. These extrapolated values will be discussed first.

In column 2 of Table II. we find the values in question for the three

TABLE II.—SEDIMENTATION VELOCITIES  $s^*$  OF POLYSTYRENES.

$$s = \frac{dr}{dt} \frac{1}{\omega^2 x}$$

$\frac{dx}{dt}$  denoting the velocity observed in the centrifugal field  $\omega^2 x$ ;  $\omega$  is the angular velocity of the rotor,  $x$  the distance of the molecule from the axis.

molecules to form spherical balls occupying a volume about ten times that of the polystyrene-thread itself, nine-tenths of the total volume being occupied by the solvent. If we suppose that all these molecules of the solvent are bound to the polystyrene threads by solvation forces and move with them in the liquid, we obtain the sedimentation velocities given in the fourth column, which agree well with the experimental values. The last column contains sedimentation velocities calculated for straight ellipsoidal particles of the length of the polystyrene molecules. In calculating these values we have taken into account the variation of the velocity with the relative orientation of the axis of the molecule, and the direction

polystyrene fractions discussed in the previous paragraph, dissolved in chloroform. It is possible to calculate hydrodynamically the velocity of sedimentation from the known molecular weight and density of polystyrenes, if definite assumptions are made as to the form of the molecules and their solvation state.

For spherical molecules without solvation-clusters the values given in column 3 are obtained. The experimental values are about half those calculated in this way, as seen by a comparison between the columns 2 and 3. Imagine now the polystyrene thread

of the field. Since the ellipsoids are continually changing their orientation by a kind of Brownian agitation, we have used an approximate mean value between the highest and the lowest possible velocity. The result can be expected to hold also for slightly curved molecules. Column 5 shows that the sedimentation of straight non-solvated molecules would be much slower than that found experimentally. Solvated molecules of the same kind, carrying molecules of the solvent with them, would have a still lower sedimentation velocity. The sedimentation velocity of diluted polystyrene solutions thus supports the theory that their molecules are curved threads forming some kind of compact cluster.

The results become different when more or less concentrated solutions of polystyrenes are considered. Fig. 1 gives a summary of experimental results, obtained with a polystyrene fraction (mean molecular weight

FIG. 1 -- Velocity of sedimentation of a high molecular styrene and of a protein with spherical particles, as a function of the concentration. Polystyrene dissolved in chloroform, molecular weight about 1,100,000. Protein (haemocyanin from *Helix Pomatia*) dissolved in water. Molecular weight about 6,000,000. Concentrations in grams per litre.

about 1,100,000); it represents the sedimentation-velocity as a function of concentration. For purposes of comparison, a curve showing the behaviour of spherical particles is included into the picture. The upper curve relates to an aqueous solution of haemocyanine obtained from *Helix Pomatia*.<sup>7</sup> This protein has a molecular weight of 6,600,000 and a molecular radius of 125 Å. If the polystyrene clusters occupied ten times the volume of the polystyrene molecules, their radius would be something of the order of 160 Å. This spherical body would be comparable in size and shape to the protein molecule, and a solution containing such clusters as dissolved particles may be expected to show no dependence of the sedimentation velocity on concentration, in analogy with the behaviour of the protein solution. The experiments reveal, on the contrary, a great difference

<sup>7</sup> See The Svedberg and E. Chirnoaga, *J. Amer. Chem. Soc.*, 1928, **50**, 1399.

between the behaviour of polystyrene solutions and that of proteins. I see no other possibility of explanation, than the assumption that the particles of dissolved polystyrene have a shape very different from that of a sphere. It seems advisable to admit at least as a working hypothesis, that the clusters of polystyrene threads are somewhat completely disentangled in solution.

The usual hydrodynamical treatment of the sedimentation of threads of this kind, at the concentrations to which Fig. 1 refers, leads also, of course, to an independence of the velocity on concentration. We may thus conclude that the usual hydrodynamical theory of viscosity does not explain the actual changes of the sedimentation velocity with concentration, and must therefore be considered as insufficient. To explain the interaction between the individual polystyrene molecules in solution, revealed by the ultracentrifuge, we must first develop a molecular kinetic theory of solutions of this kind. First, after an adequate interpretation of the sedimentation process we may hope successfully to describe the much more complicated phenomena of viscosity.

If the theory of more or less linear polystyrene threads is correct, then the polystyrene molecules must show, at low concentrations, a strong gliding against the surrounding solvent. This is the only way of explaining the high experimental values of the sedimentation velocity, as compared with those calculated theoretically for straight particles (see columns 5 and 2 in Table II.). A gliding appears not improbable, if one thinks of the small cross-sections of the threads and a certain kinetical independence of their individual sections.

On the whole, we can deduce from the sedimentation phenomena of the polystyrenes in solution, that the movement of the dissolved particles relative to the solvent is governed by laws more complicated than those so far used in the theoretical discussions of the viscosity problem. It may be suggested that the specific dependence of the sedimentation velocity on concentration is a direct proof of the long rod-shaped form of the molecules. If this were true, and the threads were not bound up into a cluster, their gliding capacity could be considered as proved.

We are now in a position to speak of the sedimentation of mixtures of two polystyrene fractions, because the phenomena observed in this case are also bound up with the thread-like structure of the molecules. Out of a mixture of spherical particles with different radii the individual particles will sediment with their own characteristic velocities, in conformity with Stokes' law: even at relatively high concentrations where will be no interaction. On this basic assumption is founded, for instance, the molecular weight analysis of protein mixtures containing components of different size.<sup>8</sup> Polystyrene fractions of very different mean molecular weights, mixed in a solution, give a sedimentation curve with discrete steps only at very low concentrations. As soon as the dilution becomes somewhat smaller (but still high enough to enable spherical particles to move with complete freedom), the sedimentation diagram of a mixture of two polystyrene fractions shows only one concentration step; the lighter and the heavier particles move with the same mean velocity.<sup>9</sup> This effect hardly can be explained otherwise than by a

<sup>8</sup> See Thé Svedberg, *Ber.*, 1935, **67A**, 117.

<sup>9</sup> Details can be found in *Helv. Chim. Acta*, 1934, **17**, 726.

mechanical entanglement of the molecules. No such entanglement would ever occur, if the single molecular threads formed compact balls; we must suppose them, on the contrary, to be more or less straight threads.

### Double Refraction of Flow.

In order to obtain more detail as to the form of polystyrene molecules in solution we made a thorough investigation of the double refraction of the flowing solutions. The following conditions were varied: the gradient of flow, concentration, molecular weight of the polystyrene and the nature of the solvent. In this case again, analogous to those of viscosimetry and of ultracentrifugation, the dilutest solutions yield the clearest result. We therefore developed the usual apparatus of Couette in order to permit readings to be taken at very low concentrations.

Certain new theories form the basis of the discussion of the phenomena. The theory of P. Boeder<sup>10</sup> is the first; this author considered the orientation of long stiff linear anisotropic particles in a flowing liquid. The degree of orientation is determined by the gradient of flow and a diffusion-constant. The latter is due to Brownian movement. The orientation of the particles determines the extinction-angle of the flowing system. The degree of orientation, the inherent anisotropy of the particles and their concentration in the solution are factors which govern the intensity of the double refraction. W. Kuhn tried to calculate the degree of orientation from the dimensions of the particles and the viscosity of the solvent.<sup>11</sup> The deductions are based on hydrodynamic formulae and doubts arise as to the possibility of using these for polystyrenes. W. Haller investigated the orientation, not only of rod-shaped molecules, but also of spherical particles, first elongated and then orientated by the flow.<sup>12</sup> The double refraction in this latter case depends not only on the gradient of flow and the Brownian movement, but also on a number of constants characterising the elastic and optical properties of the particles. In the following the most important experimental results will be described, and compared with the predictions of the orientation theory. Conformity with these predictions can be interpreted as a confirmation of the premises of the theory, i.e., of the linear form of the molecules. A comparison of the experimental results with the theory of elongated spherical particles is somewhat uncertain, owing to the great number of constants involved. We must bear in mind that under suitable circumstances the elongation effects may be not very different from the orientation effects, and the experiment may therefore be incapable of discriminating between them.

#### A. The Sign of the Double Refraction of Flow.

The double refraction of all polystyrene solutions in the usual solvents—benzene, toluene, tetraline, ethylene-bromide, bromobenzene, dioxane, etc.—is *negative* in respect to the long axis of the particle. A negative effect of this kind occurs with very few substances. It has been observed previously with poly-indene,<sup>13</sup> with esters of poly-acrylic acid<sup>14</sup> and with

<sup>10</sup> *Z. Physik*, 1932, **75**, 258.

<sup>11</sup> Quantitative discussion of the viscosity and the double refraction of flow of suspensions can be found in *Kolloid Z.*, 1933, **62**, 269.

<sup>12</sup> "Orientation and deformation of disperse particles in flowing liquids," *Kolloid Z.*, 1932, **61**, 26.

<sup>13</sup> *Z. physik. Chemie*, 1930, **150A**, 264.

<sup>14</sup> *Ibid.*, 1931, **152A**, 58.

highly nitrated cellulose.<sup>15</sup> A great number of substances with long-shaped molecules—paraffins, esters of oleic acid, caoutchouc, balata, poly-vinyl alcohol, poly-ethylene oxide, ethyl cellulose, acetyl cellulose, etc., all have a positive double refraction in solution. There exists a relation between the sign of the double refraction in solution and in the solid state. The nitro-cellulose fibre is negatively double-refractive relative to the axis of the fibre, *i.e.*, the long axis of the molecules. Isotropic films of polystyrene or esters of poly-acrylic acid become double-refractive when stretched, the double refraction being negative in respect to the direction of stress. All substances with a positive double refraction of flow show either a positive double refraction in the crystalline state (referred to the long axis of the molecule) or a positive double re-

fraction of stretched films (relative to the direction of stress). This identity of the sign of double refraction in flowing solutions and in the solid state indicates that the double refraction of flow also, is based on the orientation of anisotropic particles. Since the dissolved particles are the thread-molecules themselves, it must be possible to recognise from the sign of the double refraction of flow in what direction—that of the longest or that of shortest axis—the molecules have their highest polarisabilities (*cf.* Fig. 2).

### (a) Low Molecular Polystyrenes, with Molecular Weights from 5 to 50,000.—

All solutions show a strictly linear increase of the double refraction with the flow gradient  $G$ . This rule can be confirmed in the whole region from the

weakest currents just producing a measurable double refraction up to the beginning of turbulence. The proportionality between the optical anisotropy  $(n_y - n_x)$  and the gradient  $G$  permits the characterisation of each solution by a constant  $(n_y - n_x)/G$ , *i.e.*, the optical anisotropy corresponding to unit flow. One and the same polystyrene fraction dissolved in a given solvent gives increasing  $(n_y - n_x)/G$ -values with growing concentration. The anisotropy increases more quickly than proportional to the concentration, as shown by Fig. 3. This figure shows also the relation between molecular size and double refraction at constant concentration. If different solutions containing the same mass of

<sup>15</sup> *Z. physik. Chemie*, 1933, 165A, 172.

polystyrene per litre are compared, one finds that  $(n_y - n_x)/G$  increases roughly proportionally to the molecular weight.

It is important to be able to compare the intensity of the double refraction of flow of polystyrenes with that of some other well-defined substances. We included therefore in Fig. 3 a dotted line indicating the anisotropy of ethyl oleate in the same solvent. The double refraction of the ester is positive. The lowest molecular polystyrene contains about 100 C-atoms in the chain, oleic acid about one-fourth of this number. The double refraction of the polystyrene is approximately ten times that of the oleate. The same order of magnitude of the effects in both substances speaks rather clearly for the same cause being responsible in both cases. The assumption of an elongation of spherical balls as the cause of the double refraction of polystyrenes thus becomes

FIG. 3.—Anisotropy of different polystyrenes dissolved in cyclohexanone: (unit flow gradient). The numbers with which the single curves are inscribed are the approximate molecular weights of the fractions. The concentrations are in gm. per litre. The dotted line shows the double refraction of ethyl oleate in cyclohexanone.

less probable, since it is known that in the case of oleic acid the cause is definitely an orientation of rod-shaped molecules.

With low molecular products (molecular weight 5 to 30,000) the extinction-angle is always  $135^\circ$ , independent of gradient and concentration. The meaning of the extinction-angle is explained by Fig. 2. With molecular weights of the order of 50,000 deviations of the extinction-angle from the value  $135^\circ$  by a few degrees begin to occur, especially at high concentrations and high flow-gradients.

The constant extinction-angle  $135^\circ$  means, according to the orientation theory, that the desorientation by the Brownian movement is a much quicker process than the orientation by the flow. Under these circumstances the degree of orientation remains very small even at the

highest experimentally attainable flow gradients. In this region of small effects, theory predicts a proportionality between the double refraction and the flow-gradient. This is confirmed by experiment. With increasing molecular weight the Brownian movement becomes less intense and the desorientation slower. This is the reason why solutions of homologous polymeric substances of the same concentration, must show increasing double refraction with increasing molecular weight. This prediction is also confirmed by experiment. We may say that the double refraction of flow of low molecular polystyrenes completely confirms to the rules of the orientation theory.

FIG. 4.—Extinction-angle  $\psi$  of different polystyrenes as a function of the flow-gradient. The numbers 100,000, 190,000 and 630,000 are the approximate molecular weights of the fractions. The numbers with which the single curves are inscribed are concentrations in gm. per litre. Solvent: bromobenzene.

(b) **High-molecular Polystyrenes with Molecular Weights from 100,000 to 1,000,000.**—With molecular weights up to 300,000, the double refraction still increases proportionally to the gradient of flow. The simple relation  $(n_y - n_x)/G = \text{const.}$  still holds and the increase of the anisotropy with concentration can be represented by plotting this constant against concentration in the same way as was done in Fig. 3 for lower molecular substances. At the highest molecular weights (over 500,000) the double refraction begins to increase more quickly than proportional to the gradient of flow.

The extinction-angles are much higher than  $135^\circ$ . Fig. 4 shows the variation of  $\psi$  with the increasing gradient of flow for some polystyrene

solutions in bromobenzene. The thick lines correspond to equi-concentrated solutions with molecular weights equal to 100,000, 190,000 and 630,000 (6.2 g. per litre). The thin curves show  $\psi$  as a function of concentration for a substance with a molecular weight of 190,000.

We will try to compare the experimental results with the predictions of the orientation-theory in the case of high-molecular products too. The curve which represents the extinction-angle as a function of the flow gradient is, for all solutions, in qualitative agreement with theory. The relative positions of the group of curves corresponding to different molecular weights are also in agreement with theory. An increase of molecular weight means a diminished intensity of thermal agitation, and therefore a better orientation of molecules at the same concentration and the same gradient of flow. The extinction-angle must thus increase with increasing molecular weight. The observed variation of  $\psi$  with concentration of a given substance at constant flow is in agreement with theory. Rising concentration leads to a stronger interlacing and entanglement of the single molecules, and thus to a slower desorientation by thermal shocks. The extinction-angle must therefore become greater in accordance with the experimental result. Only at one point does experiment yield results disproving the theory: with solutions whose extinction angle differs appreciably from  $135^\circ$ , the anisotropy must be expected to increase more slowly than proportionally to the gradient of flow. The experiment shows, however, a proportionality between  $(n_\delta - n_\alpha)$  and  $G$ , and at very high molecular weight even a still more rapid increase of  $(n_\delta - n_\alpha)$ . The orientation theory does not explain this behaviour. In the following paragraph we shall try to find a form of thread molecules which could explain all the phenomena observed.

### C. Form of Polystyrene-molecules which would be in Agreement with the Phenomena of Double Refraction.

The agreement between the orientation theory and experiment at "low" molecular weights favours the assumption that the most probable form of the molecules of low molecular polystyrenes is linear. No theoretical or experimental arguments suggest, however, the assumption of rigid molecules; certain deviations from the linear form are therefore quite probable to occur. The assumption is only that an energy is necessary to bend the molecules and that they have therefore a tendency to straighten themselves out again. An explanation of this tendency will be sought later. At low molecular weights we suppose the greatest number of molecules to be present in a linear state. Their double refraction of flow is practically a purely orientation phenomenon. In going over to higher molecular products, one has to consider that with growing chain-length the form of a molecule with a given radius of curvature differs more and more from that of a straight thread. We have therefore to suppose that at high molecular weights, in addition to molecules which are more or less straight rods, there occur a great number of appreciably curved molecules of different shapes. Purely geometrical considerations explain why the contribution of the latter to the double refraction must be very small. With increasing gradient of flow the curved molecules are more and more straightened. This effect explains the rapid increase of the double refraction of high polymeric polystyrenes with the gradient, which proved to be "too quick" from the point of view of the pure orientation theory.

Very high molecular nitro-celluloses show a dependence of double-refraction on the flow gradient which is nearly in agreement with the orientation theory.<sup>16</sup> We can consider this as an indication that the deviations from the linear form are, in this case, much smaller than in the case of the polystyrenes. Stereochemical considerations support this suggestion.

The above discussed conception of the form of polystyrene molecules in solution is based on the assumption of a tendency of molecules to straighten themselves out. To make the theory plausible, one has to find an explanation for the forces which are responsible for this tendency. We bear in mind in this connection, the resistance against free rotation around the C—C bond, which has been discovered in the ethane molecule. A resistance against rotation seems, however, not to suffice as an explanation of the straight form of long molecules in solutions. The following idea may explain to some extent the tendency of molecular thread-balls to disentangle: the individual parts of the long thread molecule have, to a certain degree, the properties of small separate kinetic units. A cluster formed by a polystyrene thread is therefore comparable to a swarm of small molecules, resembling that which exists in the first moments after the dissolution of a small crystal. Sooner or later diffusion distributes the molecules of the swarm more or less evenly throughout the whole of the solution. An analogous osmotic phenomenon will cause the molecular ball to disentangle as far as possible. The linear form appears from this point of view to be only a question of statistical probability. Deviations from the straight form are effects analogous to the fluctuations of the concentration of a solution. But a statistical treatment of this kind will surely lead to results concerning the most probable form of the molecules quite different from those obtained by the purely geometrical statistics of different possible situations, as developed recently by some authors.<sup>17</sup>

#### D. Double Refraction of Flow and the Abnormal Viscosity of Polystyrene-solutions.

The solutions of lower-molecular polystyrenes have a normal viscosity—i.e., their internal friction is independent of the gradient of flow. From about the molecular weight 100,000 upwards the viscosity becomes abnormal; the internal friction decreases with increasing gradient of flow. The larger the molecules, the stronger becomes this abnormal effect.<sup>18</sup> At molecular weight 100,000 also the deviations of the extinction-angle from the value  $135^\circ$  become appreciable. They also increase with increasing molecular weight. The orientation theory demands that solutions with an extinction-angle equal to  $135^\circ$  shall have a constant viscosity. The stronger the orientation of particles in the direction of the flow (and the greater therefore the extinction angle), the smaller must be the resistances of the particles against the flow of the liquid.

This agreement between optical measurements and viscosity data from the point of view of the orientation theory forms another argument for the assumption of a more or less linear structure of the molecular threads of polystyrene. Abnormal viscosity is in this case a purely

<sup>16</sup> *Z. physik. Chem.*, 1933, 165A, 161.

<sup>17</sup> W. Kuhn, *Kolloid Z.*, 1934, 68, 2; further, W. Guth and H. Mark, *Monatsh. Chem.*, 1935, 65, 93.

<sup>18</sup> *Die hochmolekularen organischen Verbindungen*, Berlin, J. Springer, 1932, p. 188 ff.

orientation-phenomenon, and it must be possible to find quantitative relations between the extinction-angle and the internal friction.

### E. Double Refraction of Flow in Different Solutions.

In a great number of solvents—e.g., benzene, toluene, tetraline, and bromobenzene—the relative viscosities of the polystyrenes are the same. The velocities of sedimentation in the ultracentrifuge are also identical in these different solvents (if reduced to the same differences of density and the same viscosity). Another constant property of these solutions is their light-scattering (reduced to the same difference of refractive-indices). Finally, the phenomena of double refraction of flow are very much alike in all these solutions. We may therefore assume the state of the dissolved particles to be the same.

There exist a number of solvents in which all the above-mentioned properties prove to be different. The relative viscosity of polystyrene solutions in these solvents is very low, the sedimentation-velocities very high, the light-scattering extremely strong. The double-refraction of flow appears also abnormal. The extinction-angles are extremely small. The sign of the double refraction may even be changed. The phenomena are too manifold to be explained by one single cause. We may imagine that in certain liquids the molecules are strongly interlaced, in others there may be even a formation of micelles, etc. A more detailed discussion will not be possible until other classes of substances have been investigated.

---

## THE MAXWELL EFFECT IN COLLOIDS.

BY DR. A. M. TAYLOR.

*Received 21st August, 1935.*

The interpretation which is placed upon the results of measurements of streaming double refraction set up in sols has been the subject of some controversy. Signer,<sup>1</sup> Boeder<sup>2</sup> and others have supposed that the double refraction observed is the immediate consequence of orientation of the colloidal particles, produced by the continued shear sustained in the viscous medium in which they are suspended. The orientation is caused by the non-spherical nature of the particles, and the hydrodynamical forces involved are balanced against the thermal agitation, so that a statistical equilibrium is achieved in which there is a preferred direction of orientation of the longest axis of the particles. The particles are assumed either to be themselves optically anisotropic, or to be isotropic but of refractive index different from that of the surrounding liquid. In the first case the observed streaming double refraction is termed inherent or intrinsic, in the second it may be called "morphic" (*Formdoppelbrechung*). Kuhn<sup>3</sup> has taken the alternative view, and supposes that the phenomenon of streaming double refraction is essentially one of photoelasticity. The particles are assumed to be isotropic in the stationary sol, but when continued shear is set up by streaming,

<sup>1</sup> Signer and Gross, *Z. physik. Chem.*, 1933, **165**, 161.

<sup>2</sup> Boeder, *Z. Physik*, 1932, **78**, 258.

<sup>3</sup> Kuhn, *Z. physik. Chem.*, 1932, **161**, 427.

the Stokes forces of tension and compression to which the shear is equivalent, cause them to be deformed, so that strain birefringence is produced in each particle, the magnitude of the effect being proportional to the stress just as in the macroscopic case.

It will be appreciated without the need of quoting formulæ and figures that both theories are able to account for the facts, more especially since the chief experimental interest lies in the variation with shearing force of the magnitude of the effect and of the direction of the optic axis relative to the stream lines. There turns out to be little difference in the general description of the phenomenon whether the birefringence be ascribed to orientation of anisotropic or to deformation of isotropic particles. It is suggested that two effects associated with the names of Kerr and Ambronn may throw light on the problem.

### Electric Double Refraction of Colloidal Sols.

The Kerr effect, which is the production of double refraction in an isotropic liquid under the influence of an electric field, is ascribed to the orientation of the constituent particles, be they molecules or aggregates. This orientation occurs as a result of the couple exerted by the electric field upon the dipole moment of the molecule or particle; this dipole may be permanent or induced. Just as in the Maxwell effect of streaming double refraction, statistical equilibrium is set up between the forces of orientation and thermal agitation; if the molecules are optically anisotropic, or in the case of colloidal particles even if they are only anisodimensional so long as the surrounding medium is of different refractive index, then the liquid becomes doubly refracting and the optic axis coincides with the preferred direction of orientation, *i.e.* with the electric field. Information has very naturally been sought from the Kerr effect as to the shape and properties of colloidal particles, as well as from the Maxwell effect, but the two phenomena appear to have been invoked separately and not simultaneously.

The usual method of observation of streaming double refraction is that suggested by Stokes, in which the liquid is contained in the annular space between two concentric cylinders, one of which is fixed while the other rotates, so that the stream lines are concentric with the cylinders. The optic axis everywhere coincides with the stream lines in the limiting cases of large particles or of high shearing velocity (less than that at which turbulence sets in). For low shearing velocity it may tend towards the direction of the equivalent Stokes force of tension, *i.e.*  $45^\circ$  to the stream lines.

If now an electric potential difference were to be applied between the two concentric cylinders the field would be radial. The double refraction resulting would be that due to the combined effect of the two fields of force, the one mechanical and the other electrical. Assuming for the moment Kuhn's view of streaming double refraction to be true, there should be no change of optical properties of the streaming liquid on switching on the electric potential. Even if the particles are electrically anisotropic, so as to be influenced by the field, they are supposed to be optically isotropic. If they are spherical orientation of their dipole moment by the field will certainly have no effect. If on the other hand the opposite view be taken that the particles are anisodimensional then they will be affected by the application of an electric field, and if they possess in addition a permanent

dipole moment the influence of the electric field will be so much the stronger. If the particles have inherent optical anisotropy, and it is their orientation which is the cause of streaming birefringence, then on switching on the electric field there should be observed a change of direction of the optic axis of the streaming liquid; the change would be such as to tend to swing the optic axis into the radial direction. The magnitude of the change would depend upon the relative strength of the electric and mechanical forces of orientation, so that from a knowledge of some of the constants of the particle others may be inferred, *e.g.* axial ratio, dipole moment, etc. Thus considerably more information may be gained as to the character of the colloidal particle by the simultaneous study of the Kerr and Maxwell effects, than of either separately; in addition the method provides a crucial experiment to decide the truth of the two rival theories of streaming double refraction.

### Dichroism.

Ambronn<sup>4</sup> in a series of beautiful experiments showed that colloidal materials such as cellulose and its derivatives consist of micelles arranged either at random or in parallel orientation. When dyed with suitable dyes such material becomes, in the latter case, dichroic and the optic axis coincides with the direction of orientation. Freundlich<sup>5</sup> found that vanadium pentoxide sols exhibited not only streaming double refraction but also dichroism. Björnsthål<sup>6</sup> examined the dichroism of lyophile and lyophobic sols, and Preston<sup>7</sup> made use of the dichroism of adsorbed dye in determining the structure of both natural and artificial fibres. This type of dichroism is due to the fact that the dye molecule is itself anisotropic and therefore dichroic within the region of its own absorption band; the forces of adhesion of the dye molecule are directed and so likewise are those of the colloid micelle<sup>8</sup>; it follows that the orientation of the dye molecule is that of the micelles and the optic axis of dichroism of the dyed material in bulk is also the axis of birefringence of the micellar structure.

If a sol, say of cellulose acetate, is to be examined for Maxwell effect then it might also be dyed with a small quantity of "direct" dye and the streaming liquid tested for dichroism as well as for double refraction. Assuming the orientation theory of streaming double refraction, it follows that, as the adsorbed dye molecules partake of the orientation of the particles, the dichroism will always be proportional to the induced birefringence, and the optic axes will be identical. On the alternative theory of Kuhn the particles are originally isotropic, and may even be spherical as well, so that the sol only exhibits double refraction as a consequence of their photoelastic deformation. If the particles are spherical there is, on flow, no orientation, and while there may be double refraction there can be no dichroism. If the particles are isotropic but not spherical, there may be some orientation and therefore dichroism, but since the birefringence is, in Kuhn's theory, caused by deformation, the dependence of the two effects upon the velocity of shear is not likely to be the same.

### Conclusion.

In the electrical experiment suggested as being a crucial test of the two theories, a positive result would be evidence for the truth of the orientation hypothesis. A negative result, that is, zero change in birefringence on switching on the electric field, might merely indicate that the dipole moment of the particles remained zero. This could be checked from measurements of the dielectric constant, and of its temperature variation.

In the dichroism experiment, zero dichroism and finite birefringence, if this occurred not merely with a single dye but with many, would be strong proof of the deformation hypothesis, particularly if the behaviour of the dyes could be checked by observations with material in the gel condition. On the other hand, parallel behaviour of dichroism and birefringence would be evidence in favour of the orientation theory.

The University of St. Andrews.*

### GENERAL DISCUSSION.

**Dr. R. Houwink (Eindhoven)** said: Perhaps the difference between protein and polystyrene in Fig. 1 might be partly explained by assuming, in both cases, the presence of a cluster, of which the first is deformable with much more difficulty than that of polystyrene. The cause of this might perhaps be that in the protein there are present positive and negative groups, which will keep the cluster tight together, whereas such strong forces cannot be pointed to in polystyrene.

In Table I. reference is made to "real" molecular weight. Is this the molecular weight determined by the ultra-centrifuge, and is there any control which proves that this is the right molecular value indeed?

**Dr. J. H. de Boer (Eindhoven)** said: Following my suggestion of yesterday after the lecture of Professor Staudinger, I should like to ask Professor Signer what are the liquids in which he finds a low and a high value, respectively, for the double refraction of flow and in which a high one. Are his observations in accordance with my predictions on account of van der Waals' forces, *viz.*, that those liquids whose molecules resemble the constituents of the polymer physically give a high solvation, high viscosity, a low scattering of light and a strong double refraction of flow, whereas liquids differing much from the constituents of the polymers will give the reverse properties. In the first group of liquids one has to assume more or less stretched, strong solvated molecules, in the second group the polymers may be clustered together. I think this is in accordance with Professor Signer's views.

**Dr. A. M. Taylor (St. Andrews)** said: On theoretical grounds it would be of interest to examine the streaming double refraction of the same substance dispersed in a series of liquids of various refractive indices. Morphic double refraction vanishes when the refractive index of the surrounding medium equals the mean refractive index of the suspended particles, and only intrinsic and photoelastic double refraction remains. From the steepness of the curve describing, under comparable conditions of velocity gradient and viscosity, the double refraction as a function of the refractive index of the dispersing liquid, the ratio of the volume of the suspended particles to that of the liquid may be deduced.\* Deviations

\* Weiner, *Physik. Z.*, 1904, 5, 332.

from the theoretical behaviour would indicate that the liquids were not without influence upon the shape of the particles.

**Dr. F. Eirich (Wien)** said: Professor Signer and many other investigators explain the behaviour of their high molecular solutions by assuming a rodlike shape of the suspended molecules. Indeed, the elongated particle form is quite generally given as the reason for high molecular qualities. Unfortunately the practical behaviour of really rigid rods in solution is not well known. Even mathematical treatment succeeds only partially (*viz.* for the case of very strong Brownian motion), but neither this nor other approximate results are satisfactorily proved. I therefore undertook experiments with really rigid rods of well-defined axial relation. The figure (Plate I, 1) will give an idea of the rods of silk with which I worked. I am continuing the work with smaller rods exhibiting Brownian motion.

From these results one can discuss Professor Signer's experiments from another point of view. I emphasise that doubling the length of stiff rods causes a proportional increase of the specific viscosity. Further the molecules with which Professor Signer worked, which were doubtless agitated, must, if they were rigid have given rise to a greater increase in the viscosity. Of course the dependence of the sedimentation velocity on concentration indicates an elongated particle shape. But such long particles, if completely straight, would give rise to a further anomaly. There is also no reason to assume a gliding. In accordance with the hydrodynamical assumptions all these long-chain molecules with their substituents on the sides attached to liquid molecules are sufficiently large to disturb the flowing. Since even sugar molecules and hydrated ions seem to satisfy the hydrodynamical equations it follows that dimensions about ten times greater than those of the fluid molecules satisfy the hydrodynamical calculations. This argument and the fact that really rigid rods can bring about the same enormous viscosity effects as high molecular bodies enables us to explain Professor Signer's effects as due to moderately long coils into which the longer chains have become entwined.

**Professor H. Mark (Wien)** said: The interesting measurements of Professor Signer give an important contribution to our knowledge concerning the form of large molecules in diluted solution and I agree entirely with him that the ultracentrifuge and the investigation of the double refraction are of the greatest importance. I think also that all our present knowledge on viscosity, sedimentation, velocity, double refraction and osmotic pressure points in a certain direction concerning the shape of macromolecules in the dissolved state.

The chain-like macromolecules, which must be investigated in extremely diluted solution seem not to be compact, more or less sphere-like clusters (compare, for instance, Fig. 2a). They are, moreover, not quite extended and stiff with elastic vibrations (as shown in Fig. 2b), but they are in a state, as it is shown in Fig. 2c, that is to say, they are bent but not rolled entirely together. If one assumes the form shown in Fig. 2c one gets in fairly good agreement with all experimental evidence (Staudinger-equation, sedimentation velocity, double refraction) and remains at the same time in concordance with fundamental statistical considerations and with the principle of the free rotation round the single carbon bond. I think that the shape shown in Fig. 2c may be regarded as a close approximation to the real form of the long molecules in solution.

**Professor H. Staudinger (Freiburg i Br.)** said: The accurate knowledge of the shape of organic molecules is of general importance, since the physical properties of an organic substance in the solid or liquid state and in solution do not only depend on the constitution but also on the shape of the molecules.<sup>10</sup> Take, *e.g.*, the glycol esters. If one wishes to express in the chemical formula the physical properties of the molecules,

<sup>10</sup> H. Staudinger, *Z. Elektrochemie*, 1934, 40, 434.

then the glycol esters should be written <sup>11</sup> according to formula 1 and not formula 2 :

I.

II.

In the solid state the shape of the molecules can be elucidated by X-ray analysis which, however, in the above mentioned case has not yet been carried out. In solution the shape of the molecules can be determined by viscosity measurements, because the validity of the viscosity law  $\eta_{sp}(1.4 \text{ per cent.}) = \gamma \cdot \eta$  in the case of long chain paraffins, ethers, esters, acids, both for saturated and unsaturated derivatives, proves that the thread molecules in these solutions possess a long extended shape. In these cases the viscosity of the solution, as expressed in the above formula,

FIG. 2.

is chiefly determined by the length of the molecules and is largely independent of their diameter. When these thread-like molecules are substituted in the side chains, the viscosity of a 1.4 per cent. solution remains unchanged. Thus equally concentrated solutions of squalene and squalene hexabromide possess equal specific viscosities though the molecular weight of the latter compound is approximately twice as great as that of the former. Hence the shape of the squalene molecule is not altered by bromine substitution. The following fact shows that the thread molecules must possess a strong degree of rigidity: in the case of acetyl celluloses and nitrocelluloses the molecular weights as determined by the viscosity method and by the osmotic method agree very well with each other.<sup>12</sup> This idea is further strengthened by the remarkable stability of high molecular weight compounds and by the fact that even organic substances of a somewhat complicated nature crystallise readily. This could not very well be understood if the shape of the molecules in solution and in the solid state were very different. One is forced to assume that the shape

<sup>11</sup> In the above formulation tetramethylene glycol ester was chosen as example and not ordinary glycol ester, since in the latter a little complication occurs; compare H. Staudinger and H. Schwalenstöcker, *Ber.*, 1935, 68, 727.

<sup>12</sup> Compare this vol., p. 110.

of the molecule in the crystalline state is essentially preserved in solution, as has been proved in the cases of the paraffins, fatty acids and their esters,<sup>13</sup> polyethylene oxides,<sup>14</sup> and cellulose and their derivatives,<sup>15</sup> for the X-ray crystal structure analysis of these substances has led to the same shape of the molecules as can be deduced from the viscosity measurements of the dissolved molecules.

Of course, thread molecules in solution cannot be compared with entirely rigid rods, but with very thin elastic rods, in which elastic oscillations about a mean position occur, these vibrations becoming larger and larger with increasing temperature. Otherwise it could not be understood why such compounds undergo intramolecular reaction with ring formation.

Mr. J. Boulton (*Braintree*) said: When cellulose is dyed with direct dyes it is believed<sup>16</sup> that the filamentary dyestuff molecules are oriented lengthways in the direction of glucose chains and are held thus by the residual valency forces exerted by OH groups on the inner surfaces of cellulose crystallites. It is this orientation which gives rise to the dichroism which is evident in cellulose bodies dyed with direct dyes. With regard to the second part of Dr. Taylor's paper, experimental difficulties arise when we attempt to imitate these conditions in a sol. It is a simple matter to prepare a sol from esterified celluloses, but the considerations stated above with reference to direct dyed cellulose do not hold with esterified cellulose which in any case does not absorb the "dichroic" direct dyes; the present speaker is acquainted with no coloured bodies which are absorbed appreciably by cellulose acetate and which exhibit dichroic behaviour. If bodies were found which exhibited dichroism on acetate cellulose it is, further, highly likely that they would as strongly associate with any cellulose acetate solvent as with the material itself. The principal difficulty appears to be getting a cellulose sol in which the behaviour of absorbed direct dye could be studied.

Dr. A. M. Taylor said in reply: "It is regrettable that for chemical reasons the second method, that of staining the macro-molecules by oriented adsorption of a suitable dye, and observation of the dichroism induced by flow, appears to be difficult in practice. It is to be hoped that the method, which on theoretical grounds would be very fruitful, may perhaps prove useful in special cases; it is of less general application than the first method suggested of crossed electric and hydrodynamical fields. The simultaneous observation of the Kerr and Maxwell effects should be valuable in every case except the special one when the macro-molecule possesses only a negligible dipole moment."

Professor R. Signer (*Bern*), in reply: Dr. Houwink suggests that the striking decrease in the sedimentation velocity of polystyrene may be explained on the assumption that in solutions at rest, coils or clusters may be formed which are very readily deformed, and that on streaming in the capillary viscometer or in the centrifuge cell the coiled thread molecules would be more or less extended. This explanation is, from many points of view, attractive but it presents many difficulties. If polystyrene solutions are sedimented in strongly varying centrifugal fields we find a proportionality between  $ds/dt$  and  $\omega^2x$ .<sup>17</sup> If deformation occurred with increasing velocity there would be no proportionality of this kind. The sedimentation experiments which have so far been carried out provide no

<sup>13</sup> Compare H. Staudinger, *Z. Elektrochemie*, 1934, 40, 434.

<sup>14</sup> Compare E. Sauter, *Z. physikal. Chem.*, 1933, 21B, 161.

<sup>15</sup> On the form of the cellulose molecule in the solid state, compare Sponsler and Dore, *Colloid Symposium Monograph*, 1926, 174 and further, K. H. Meyer and H. Mark, *Ber.*, 1928, 61, 593. On the shape of the cellulose molecule in solution, compare H. Staudinger, *Die hochmolekularen organischen Verbindungen, Kautschuk und Cellulose*.

<sup>16</sup> Meyer, *Melliand*, 1928, 9, 573; 1929, 10, 31.

<sup>17</sup> *Helv. Chim. Acta*, 1934, 17, 64, Table III.

confirmation of Dr. Houwink's interpretation. Further, the linear increase in the streaming double refraction with the velocity gradient gives evidence against an unravelling of coils. On the other hand, we do still find ourselves in harmony with experiment, if we assume that in fluids at rest the threads are fully extended.

In reply to Dr. Houwink's other question, the molecular weights in Table I. were determined by means of the ultracentrifuge; *i.e.*, from the sedimentation equilibrium. With regard to the accuracy of these values, one can only say that in very dilute solutions there are no osmotic complications.

FIG. 3.—Streaming double refraction of a high polymeric styrene in solvents of different refractive index. Concentration: 13 g polystyrene per litre of solution. Streaming gradient:  $G = 50 \cdot \frac{1}{\eta}$ , where  $\eta$  is the absolute viscosity of the solvent.

The questions of J. H. de Boer and A. M. Taylor are answered by Fig. 1. It shows the dependence of the streaming double refraction of a polystyrene (mol. wt. about 100,000) on the refractive index of the solvent. The figure shows that purely rod-like morphic double refraction, without intrinsic double refraction, cannot exist. A curve can be drawn through points 1, 2, 4, 6, 7 and 8 which corresponds qualitatively to an interaction of negative intrinsic double refraction and rod-like morphic double refraction. The values for a mixture of dioxane and water as solvent and for tetraline lie off the curve (points 3 and 5). Clearly these

media have but slight solvent affinity for polystyrene. The conditions for solution are here different, as is to be inferred from other properties, such as viscosity, degree of turbidity, etc.

*In reply to Mark and Eirich:* The experimental conditions in polystyrene solutions can be best understood if we assume that relatively short molecules exist exclusively in the stretched form. Very large molecules will also exist in the curved form. The assumption of a tight coiling is scarcely compatible with experimental observation, at any rate in solvents with good solvent capacity. The tendency towards coiling is well understood as an osmotic effect.

## SOME OBSERVATIONS ON POLYSTYRENE AND ON THE MECHANISM OF POLYMERISATION.

By G. STAFFORD WHITBY.

*Received 7th August, 1935.*

Leaving aside the case of such materials as carbohydrates of high molecular weight, which cannot be regarded as polymers in the sense of substances formed by the repetition in a single molecule of a monomeric unit known to exist separately (no simple unit,  $C_6H_{10}O_5$ , is known from which cellulose  $(C_6H_{10}O_5)_n$  is obtainable), and in the formation and behaviour of which secondary valency forces associated with the oxygen bridges may possibly play an important part, in typical cases the occurrence of polymerisation is dependent on the presence in a monomeric unit of an unsaturated centre, such as  $C:O$ ,  $C:N$  or, most frequently,  $C:C$ , and the repetition of such a unit in single molecules to form polymers is, according to the consensus of present-day opinion, due to primary valencies.

Studies of the polymerisation of a number of unsaturated compounds, which are capable of yielding polymers ranging up to material of high molecular weight, and including prominently compounds containing a conjugated system, especially butadienoid hydrocarbons and compounds containing a semi-benzenoid system, and, particularly, detailed studies of the polymers of indene, led the writer to the view that the union of monomeric molecules to form polymers is typically due to a succession of additions, of the ordinary, chemical type, to the double bond present in the monomer or the preceding polymeric stage, an atom of hydrogen going to one side of the double bond and the rest of the addendum to the other. For example:—

the degree of polymerisation. Brunner,<sup>7</sup> working with Staudinger, measured the bromine absorption of polystyrene preparations higher than those listed in Table III., with the results in Table IV.

In these experiments, however, an absorption period of only one hour was allowed. In the experiments on which Table III. is based an absorption period of twenty-four hours was given. But even the latter period is apparently insufficient for the completion of bromine addition, to judge

by experiments of Staudinger and Steinhöfer<sup>8</sup> published since the writer's work on polystyrene was completed. These authors found the results on Table V. for the bromine addition capacity of two samples of polystyrene (prepared by the action of stannic chloride on styrene).

It thus seems probable that, had a longer period of absorption than twenty-four hours been given in the experiments noted in Table III., the

bromine addition of all samples would have been equivalent to two atoms per mole.

In view of the above data, it seems reasonable to suppose that polystyrenes, like polyindenes, contain one double bond per molecule, no matter what the size of the polymer.

Additional evidence for the unsaturated character of polystyrene

<sup>7</sup> Brunner, *Dissertation*, Zurich, 1926.

<sup>8</sup> Staudinger and Steinhöfer, *Annalen*, 1935, 517, 35.

and polyindene is to be seen in the work of Gallay,<sup>9</sup> who measured the dipole moment of a series of these polymers and found it to increase with increasing molecular size—a fact explicable only on the view that a double bond persists after polymerisation.

A recent study of the polymerisation of indene made by Risi and Gauvin<sup>10</sup> indicates that a further complication may in some cases arise from the occurrence of molecular rearrangement of the first-formed unsaturated polymer to a saturated compound (the ordinary, unsaturated diindene, for example, can be transformed, by heating, into a saturated isomer). This study does not, in the writer's opinion, invalidate the view of the mechanism of polymerisation here in question. It does, however, perhaps suggest that in studies directed to the elucidation of the mechanism of polymerisation it is wisest to choose cases where polymerisation can be brought about—by suitable catalysts or by mere standing—without the application of high temperatures. Such cases should preferably be chosen so that the products are of moderate molecular size only, since very highly polymerised materials such as spontaneously-polymerised styrene are intractable.

### Addition of Monomer and Polymer.

Further evidence in support of the view enunciated as to the mechanism of the polymerisation, *viz.* that it is a succession of ordinary chemical addition reactions, is found in the fact that when a mixture of indene and diindene or of styrene and distyrene is heated higher polymers are formed. That the addition of monomer and dimer is involved in this reaction is shown by the fact that the amount of higher polymer formed is in excess of that which could have been derived from the amount of monomer which disappears.

A mixture of equal parts of styrene and distyrene heated for four days at 240° C. gave<sup>3</sup> 76 per cent. of polystyrene, as a white amorphous solid with a mean molecular weight of 1316, equivalent to a polymerisation degree of nearly 13. A mixture of indene and diindene gave triindene when heated together.<sup>3</sup> The lower degree of polymerisation attained in the latter case, as compared with the case of mono- and di-styrene, is in accord with the fact that in general indene does not yield such high polymers as styrene, especially when heat is used as the polymerising agency.

Experiments carried out by Houtz and Adkins<sup>11</sup> show that a higher stage in the polymerisation process can be secured by causing a lower stage and monomer to react. They showed that polystyrene of very high molecular weight and styrene are capable of adding together when heated, yielding a polystyrene of still higher molecular weight. Mixtures of styrene and polystyrene when heated together gave a yield of polymer markedly greater in amount and higher in molecular weight than was given by styrene heated alone under the same conditions.

The fact established by these various experiments that monomer and a lower polymer are capable of adding together to form a higher polymer clearly supports the view that a succession of stepwise additions is involved in the formation of long chains by polymerisation.

Further in accord with this view is the fact that it has in several cases been shown that the unsaturated molecules which represent early members in the polymerisation scheme are themselves polymerisable, albeit, as might be expected, more sluggishly than are the monomers. Diindene heated

for twenty-one days at  $214^{\circ}$  C. gave 81.4 per cent. of a polyindene with a mean molecular weight of 562, corresponding to a mean degree of polymerisation of nearly 5. Treated with the polymerisation catalyst, antimony pentachloride, it gave a polymer of molecular weight 1233, corresponding to a degree of polymerisation of 10. Distyrene heated for four days at  $245^{\circ}$  C. showed indications of polymerisation, the molecular weight rising from 204 to 302. Staudinger and Steinhöfer<sup>8</sup> have found that distyrene and tristyrene are polymerised by treatment with stannic chloride to the stage of a tetramer and a hexamer of styrene respectively.

### Pyrolysis of Polymers.

In the case of a polymeric product, such as rubber, derived by the polymerisation of a diolefine, pyrogenic decomposition is of very limited value for the purpose of elucidating the constitution of the polymer, because of the occurrence of cyclisation in the open-chain terpenic fragments which may be supposed to represent the initial products of cracking. In the case of polymers, such as polyindene and polystyrene, derived from semi-benzenoid monomers, pyrogenic decomposition is, however, a more illuminating and less ambiguous line of investigation. When subjected to pyrolytic distillation, both polyindene and polystyrene behave in a way that accords with the conception of their constitution which has already been outlined. They undergo a typical cracking reaction, which is the converse of the reaction conceived to take place in their formation: the chain undergoes scission into fragments with the simultaneous wandering of a hydrogen atom and the appearance of a double bond for each fragment. When the temperature applied is sufficient to produce scission products which are distillable under reduced pressure, these products are—monomer, dimer, trimer, and low polymers. (When the temperature is insufficient to yield distillable products, the result of heating is to "crack" the large polymeric molecules to smaller, but still relatively large ones. Thus, *e.g.*, a sample of polyindene of mean molecular weight 2631, when heated for fifteen days at  $214^{\circ}$  C., gave no distillable products but suffered a reduction in molecular weight to 870.<sup>2</sup>)

The following Table shows the fractions obtained by the pyrolytic distillation under a pressure of 2 mm. of two fairly homogeneous samples of polyindene of different molecular weights<sup>2</sup> :—

In the experiments both with polyindenes and polystyrenes, it was found that the more highly polymerised sample broke down more readily, *i.e.*, at a lower temperature, and more profoundly, *i.e.*, to yield a larger proportion of the smaller cracked products, than did the less highly polymerised sample. This is in accord with what happens in the cracking of simple, non-polymeric molecules. The straight-chain paraffins, for example, crack more readily, the longer the chain.<sup>13</sup>

### Importance of Terminal Hydrogen Atoms.

The hypothesis of the mechanism of polymerisation here under discussion involves as an essential feature the wandering at each step in the process of a hydrogen atom from one molecule to the unsaturated system present in the molecule of the monomer or of an earlier polymeric stage. In accord with it is the fact that terminal substitution in the butadienoid system is unfavourable to polymerisation. Piperylene (1-methylbutadiene) polymerises less readily than isoprene (2-methylbutadiene).<sup>14</sup> Of the dimethylbutadienes, the 2:3-compound, in which all the terminal hydrogen atoms of butadiene are unsubstituted, polymerises more readily and to a product of higher molecular weight than any of the others; the 1:4-compound, in which both terminal hydrogens of butadiene are substituted, polymerises least readily.<sup>15</sup> The 1:1:4-trimethylbutadiene has far less capacity for polymerisation than the corresponding 1:1:3-compound. The trimethyl compounds polymerise less than corresponding dimethyl compounds. The 1:1:4:4-tetramethylbutadiene, in which all the terminal hydrogens of butadiene are substituted, is practically or entirely devoid of ability to polymerise,<sup>14</sup> but the 1:2:3:4-compound

<sup>15</sup> Whitby and Gallay, *Can. J. Res.*, 1932, 6, 280.

shows some capacity for polymerisation, a pentamer being isolated from it.<sup>15</sup>

A similar state of affairs holds for the phenyl-substituted butadienes: the greater the amount of substitution, especially in the terminal positions, the lower is the tendency to polymerisation.<sup>15</sup>

Carothers<sup>16</sup> has observed similar conditions among the homologues and analogues of the highly polymerisable molecule, chloroprene (2-chlorobutadiene). Whereas alkyl substitution in the median position of the butadienoid system does not seriously affect the polymerisability of chloroprene, terminal substitution reduces it markedly, and, the larger the terminal alkyl substituent, the more seriously is the ease of polymerisation reduced. Similarly, the introduction of one or two additional chlorine atoms into chloroprene, if in the terminal positions, greatly reduces the ease of polymerisation.

### Caoutchouc.

The motive behind much of the study which has in recent years been devoted to polymeric materials and to the mechanism of polymerisation has been the desire to elucidate the constitution of the important, naturally-occurring materials, rubber and cellulose. The writer has considered the question of the constitution of caoutchouc, the hydrocarbon of rubber, from the point of view of the hypothesis, outlined above, that the formation of high polymers from unsaturated compounds involves a succession of ordinary, chemical additions with wandering of hydrogen atoms.<sup>17</sup> He has pointed out that there are three possible schemes according to which isoprene molecules might on this hypothesis undergo stepwise addition in a regular manner. Each of these leads to the formulation of caoutchouc as containing, by virtue of the presence of a terminal diolefinic system, one double bond more than the number of isoprene units involved. The following is one of the schemes in question and involves the 1:4-addition of isoprene molecules in a stepwise and regular manner:—

On ozonolysis such a molecule would yield  $\alpha$  molecules of lævulinic aldehyde or acid, and one molecule of each of the following: formaldehyde or formic acid, methylglyoxal or pyruvic acid, acetaldehyde or acetic acid, aceto-acetic acid or aldehyde. It was pointed out that, while the work of Harries had made it clear that, as would be expected if  $\alpha$  were large in a formula such as the above, the ozonolysis products of caoutchouc are preponderantly lævulinic aldehyde and acid, it might be expected that, if such a formula were correct, a careful re-examination of the products of the ozonolysis of caoutchouc made with a sufficiently large amount of material would disclose the occurrence in small amounts

<sup>17</sup> Whitby, *Trans. Instn. Rubber Industry*, 1929, 5, Pt. 1.

It is interesting to note that Staudinger, who has carried out extensive investigations on the subject of polymerisation, after exploring other modes of formulation for polymers, appears in some of his more recent writings to be disposed to consider that the molecules of long-chain polymers contain a terminal double bond. Staudinger originally<sup>19</sup> held the view that free valencies existed at the ends of the molecule of long-chain polymers, but<sup>20</sup> did not make themselves evident in the possession of unsaturation by the molecule because of the large size of the latter. He supposed, for example, that caoutchouc had the formula—

In the case of the long-chain polyoxymethylenes prepared by the action of various reagents on formaldehyde "foreign" groups were found by Staundinger at the ends of the chains, and he has sought without success to identify such in long-chain polymeric hydrocarbons. And in his latest paper on polystyrenes<sup>8</sup> he has recognised these materials as unsaturated and appears inclined to consider that a terminal double bond is present in their molecules. He supposes that after polymeric chains with free end valencies have built themselves up by a chain reaction between monomeric molecules, wandering of hydrogen from one chain to another occurs with the consequent formation of a double bond, as follows:

Of the various artificial polymers known to exhibit elastic properties, polystyrene, which was first observed by the author to show elastic properties under appropriate conditions,<sup>23</sup> perhaps most deserves being described, as Staudinger has described it, as a "model of caoutchouc."

<sup>32</sup> Whitby, *Colloid Symposium Monograph*, 1926, 4, 203.

A study<sup>23</sup> of the colloidal and elastic properties of the two materials discloses many analogies between them. Polystyrene and rubber act similarly in regard to their behaviour to organic liquids, in regard to the nature of the liquids in which they swell and ultimately disperse, and in regard to the relative ease with which they are precipitated from their sols by, for example, the homologous series of aliphatic alcohols. Sols of polystyrene and of rubber are also similar in that the relative viscosity is not affected by change of temperature, and in that it is reduced by heating, mechanical agitation and exposure to ultra-violet light.

Although hard and inelastic at room temperature, polystyrene of high molecular weight shows at an elevated temperature (e.g., 70°), elastic properties similar to those of rubber in regard to extensibility, retractive ability, elastic after-effect, set, etc.

The most significant observation is perhaps that the colloidal and elastic properties are quantitatively influenced by the molecular weight. Polystyrene of very high molecular weight (prepared by the spontaneous polymerisation of styrene) is similar to raw rubber in the ease with which it retracts after being extended. Polystyrene of relatively low molecular weight (prepared by the heat polymerisation of styrene) shows very much poorer elastic properties; while very readily extensible, its ability to retract is poor. Thus, for example, a sample of molecular weight about 2000, when extended 800 per cent. and then released retracted to 600 per cent. only.

The solubility is also influenced by the degree of polymerisation. For example, polystyrene of very high molecular weight is unaffected by ether, acetone and ethyl oxalate, whereas polystyrene of relatively low molecular weight rapidly disperses in them.

## THE INSOLUBLE POLYSTYRENE.

BY PROFESSOR DR. H. STAUDINGER, *Director of the Chemical Laboratories,  
University of Freiburg (Breisgau)*, IN COLLABORATION WITH  
DR. W. HEUER AND DR. E. HUSEMANN.

Communication No. 121 in the series "*Über hochpolymere Verbindungen*."

*Received 4th July, 1935, in German and translated by  
DR. I. J. RABINOVITCH.*

The following interesting observation has been made by colloid chemists: Certain lyophilic colloids, although apparently of equal composition, show a very different capacity of swelling and dissolution.<sup>1</sup> Some of them swell to an unlimited extent, lose their form and finally dissolve completely. Other colloids, apparently chemically identical with the first, swell only up to a certain limit. Treated with the same

<sup>1</sup> See e.g. the monographs by J. R. Katz, in *Kolloidchem. Beihe.*, 1917, 9, 1; and *Ergebnisse der exakten Naturwissenschaften*, 1924-25.

solvents as those of the first kind, they retain their form and remain undissolved even after a long treatment with large quantities of the solvent. At the same time, their capacity of swelling may be very extensive; the volume of the substance being increased by swelling to about 50 or 100 times its initial value.

Many natural products with a highly polymeric structure have modifications of these two kinds. We may mention for instance the two modifications of indiarubber. Besides the ordinary, soluble and unlimitedly swelling product, there exists an insoluble modification with a limited swelling capacity.<sup>3</sup> The two are known as  $\alpha$ - and  $\beta$ -caoutchouc.<sup>3</sup> They cannot be distinguished by chemical analysis. In the case of some proteins, too, insoluble forms, with a limited swelling-capacity are known in addition to other modifications—hardly distinguishable from the first by chemical analysis, but soluble and swelling without limit. If such important differences of physical properties occur with substances of relatively low molecular weight, they can usually be traced back to variations in the chemical structure. In the case of the colloids in question, no differences of chemical constitution could at first be detected, and their different behaviour has therefore been described as a "colloidal phenomenon." The explanation of the solubility of the one and the insolubility of the other modification was sought in their different micellar structure rather than in a different molecular constitution, as in the case of low molecular substances.

The investigations of highly-polymeric *synthetic* substances revealed, however, that this point of view cannot be correct. Even in the case of colloids, the variations of the physical behaviour are due to chemical differences in the molecular structure. The "macro-molecules" of the soluble colloid with their unlimited swelling capacity, are different from those of the insoluble colloid of similar composition. The proof given is based, firstly, on experiments with synthetic polystyrenes. A soluble modification of this highly polymeric substance was prepared, in addition to an insoluble one.<sup>4</sup> Both are products of eucolloidal nature—tough, vitreous substances, which appear to be identical. They both swell with organic solvents—benzene, carbon tetrachloride, carbon disulphide. But whereas the molecules of the first modification are removed from the surface by the action of the solvent—dissolution occurring simultaneously with swelling, the second substance does not dissolve during the swelling and retains therefore its original form, as shown in Plate I, 2. Chemical analysis reveals no difference between the two products, despite their different behaviour to solvents. The two substances *are*, however, different in their chemical constitution (and not, as might be supposed, in their micellar structure). But this difference can hardly be detected by analysis. The difference is revealed by the methods of producing the two modifications synthetically.

The polymerisation of pure styrene<sup>5</sup> leads to the "polystyrenes," possessing long thread-shaped molecules. The actual length of the

<sup>5</sup> H. Staudinger and E. Husemann, *Ber. Chem. Ges.*, 1935, **68**, 1618; H. Staudinger and W. Heuer, *Ber. Dt. Chem. Ges.*, 1934, **67**, 1164.

<sup>6</sup> See H. Staudinger, *Die hochmolekularen organischen Verbindungen, Kautschuk und Cellulose*, Verlag J. Springer, Berlin, 1932, the paper with W. Heuer, p. 157.

threads depends on the conditions of polymerisation: Slow polymerisation at low temperatures gives eucolloidal polystyrenes; their order of polymerisation is not less than 1000 to 5000. Rapid polymerisation with the help of catalysts (for instance, tin tetrachloride) gives hemicolloidal powders, with a degree of polymerisation of not more than 50 or 100. All these products are soluble in organic solvents. The hemicolloids dissolve without swelling, the eucolloidal products swell strongly during the dissolution.

If a small quantity of *para*-divinylbenzene is added to the styrene before polymerisation, and the latter carried out at about 60-100° C. a mixed polymeric product of styrene and divinylbenzene is obtained. Its outer appearance is the same as that of the pure polystyrene prepared under the same conditions: it is a tough, hard glass. But its solubility is quite different: the "mixed" product is insoluble in organic solvents, although it can be swollen by them to a very high degree. The addition of divinylbenzene has thus transformed the soluble polystyrene, with its unlimited swelling capacity, into an insoluble product with a restricted capacity of swelling.

The explanation must be sought in the formation of a kind of divinyl benzene "bridges" linking together the thread-molecules of the polystyrene, as illustrated by the following formula<sup>6</sup>:

As shown by this formula, the "mixed" polymeric substance is composed of macro-molecules extending in all three dimensions, and not of simple thread-molecules, as was the case with the "pure" polystyrene.

The quantity of divinylbenzene which is required to obtain the insoluble product instead of the soluble one, is exceedingly small. One molecule of divinylbenzene is enough for 10,000-50,000 molecules of the monomeric styrene (depending on the conditions of polymerisation). This corresponds to an addition of about 0.01-0.002 per cent. of divinylbenzene—a change of composition which cannot be discovered by ordinary

\* H. Staudinger and W. Heuer, *Ber., Dt. Chem. Ges.*, 1934, **67**, 1166.

chemical analysis. It is not surprising, therefore, that the two polystyrenes appear to be identical when studied analytically. It is only by their synthesis that light is thrown on the differences in the structures of the two modifications.

The smallness of the quantity of divinylbenzene sufficient to cause such an important change in the physical properties of the polystyrenes is due to the fact that the soluble polystyrene is composed of very long chain-molecules. It is sufficient to establish some few links between adjoining macro-molecules in order to make a dissolution of the substance impossible. The swelling-capacity remains, because the molecules retain their tendency to form solvates; but even after solvation they cannot leave the bulk of the substance, because they are linked together by the "bridges" formed by divinylbenzene.

### Mixed Polymeric Products with Different Concentrations of Divinylbenzene.

After having elucidated the cause of the formation of insoluble polystyrene, we proceeded to the preparation of polystyrenes contain-

FIG. 1.

ing different proportions of divinylbenzene, in order to investigate the influence of the number of links between the molecular chains on the swelling-capacity of the product. In accordance with our anticipations, we found, as a general rule, a decrease in swelling capacity with increased concentration of divinylbenzene. This is illustrated by Table I. and Fig. 1.

If the concentration of divinylbenzene is higher, products are obtained which hardly show any swelling at all. Pure para-divinylbenzene gives when polymerised at 60-100° C. a product which out-

wardly resembles the polystyrenes obtained under the same conditions. Like eucolloidal polystyrenes, these poly-divinylbenzenes are vitreous substances; but they differ from polystyrenes in that they have no swelling capacity whatsoever. The poly-divinylbenzenes are very brittle and can easily be powdered. This difference of mechanical properties is explained by the building up of poly-divinylbenzenes from three-dimensional molecules, instead of the thread-shaped molecules of the polystyrenes. The structure can be symbolised as follows: <sup>7</sup>

<sup>7</sup> H. Staudinger and W. Heuer, *Ber. Dt. Chem. Ges.*, 1934, **67**, 1167.

\* After deducting the amount of styrene extracted by the solvent.

This is another proof of the close connection between the mechanical stability of the polystyrenes (and similar polymeric products) and the long thread-form of their molecules.

The polymeric products with limited swelling capacity are connected to the pure polystyrenes by a whole series of intermediary forms. When the proportion of divinylbenzene becomes very small, the mixed polymeric substances show a very high swelling capacity and contain at certain amount of soluble polystyrenes, which can be extracted by the solvent without changing the form of the remaining body. A comparison between columns 3 and 5 of Table I. shows that the swelling becomes higher with an increased proportion of soluble matter in the insoluble product.

At still lower concentrations of divinylbenzene, the polymerised product no more retains its form in swelling. The linking of the polystyrene-macro-molecules by divinylbenzene bridges becomes too weak to hold the substance together. If the concentration of divinylbenzene is decreased still further, the whole substance becomes soluble. But even after dissolution, the polystyrene-molecules remain linked to groups by divinylbenzene-links; the average length of the dissolved molecules is therefore greater than in solutions of pure polystyrenes and the viscosity of the solution therefore higher. A polystyrene obtained by polymerisation of pure styrene at 100° C. has for instance a viscosity  $\eta_{sp}/c = 21.5$ . With a divinylbenzene concentration of 0.0025 per cent., the product obtained under the same conditions is still soluble, but its solution has a much higher viscosity:  $\eta_{sp}/c = 41.6$ . This indicates clearly that the molecules of the "mixed" polymer are larger than those of the pure polystyrene.

### Mixed Polymeric Products with Polystyrene-Chains of Different Length.

We further investigated the connection between the length of the polystyrene-chains and the amount of divinylbenzene required for obtaining an insoluble product. We first polymerised pure styrene under different conditions and determined the length of the polystyrene-macromolecules obtained in different cases. We then polymerised mixtures of styrene and divinylbenzene under the same conditions and determined the smallest amount of divinylbenzene which gave a polymeric product with limited swelling capacity, capable of retaining its form after swelling. Under the conditions in which hemicolloidal polystyrenes were formed, the amounts of divinylbenzene necessary for the polymers to become insoluble were much larger than in the case of eucolloidal products, with their longer chain-molecules. Table II. shows how widely different are the proportions of divinylbenzene under different conditions.<sup>8</sup>

TABLE II.—MINIMUM AMOUNTS OF DIVINYLBENZENE REQUIRED FOR THE PRODUCTION OF A POLYMER WITH LIMITED SWELLING CAPACITY, WITH DIFFERENT LENGTHS OF POLYSTYRENE-CHAINS.

1.	2.	3.	4.	5.	6.	7.
Pure Polystyrene.	Conditions of Polymerisation.	$\eta_{sp}/c$ .	Order of Polymerisation of the Pure Polystyrene.	Chain-length in Å.	Number of Mols. Styrene per Mol. Divinylbenzene.	Per Cent. Concentration of Divinylbenzene.
Hemicolloid	20 per cent. styrene-solution in benzene + 0.4 per cent. $\text{SnCl}_4$ , at $0^\circ$	0.54	30	75	1	55
	Pure styrole + 0.4 per cent. $\text{SnCl}_4$ , at $0^\circ$	1.3	70	175	6	17
Mesocolloid	Pure styrene at $200^\circ$	4.3	240	600	1,000	0.1
	Pure styrene at $150^\circ$	8.9	510	1,275	7,500	0.012
	Pure styrene at $120^\circ$	15.1	840	2,100	15,000	0.006
Eucolloid	Pure styrene at $100^\circ$	21.5	1,200	3,000	30,000	0.003
	Pure styrene at $80^\circ$	30.6	1,700	4,250	50,000	0.002

Table II. shows that no direct *proportionality* exists between the amount of divinylbenzene required for making the product insoluble and the chain-length of the polystyrene. This amount is relatively much higher for hemicolloidal products than for eucolloidal polymers. It is therefore impossible to calculate the length of the polystyrene-chains from the amount of divinylbenzene which makes them insoluble (we hoped first to find in this way a possibility of determining chemically the chain-length of the polystyrenes). Only as a general conclusion can be drawn from these investigations the fact that the polystyrene-chains are very long, since such a small amount of divinylbenzene is sufficient to link them together. The experiments show further, that in the eucolloidal polymers with limited swelling capacity not the whole of the polystyrene molecules are linked together by divinylbenzene-bridges, but

<sup>8</sup> H. Staudinger and E. Husermann, *Ber.*, 1935, **68**, 1618.

only a part of them. These substances must represent closely interwoven mixtures of three-dimensional macro-molecules of the "mixed" polymer with the thread-molecules of the pure polystyrene.

### Swelling in Different Solvents.

In a previous paper<sup>9</sup> we have shown that the solubility of the polystyrenes is very different for different solvents. There exist a number of solvents, *e.g.*, benzene, carbon disulphide, carbon tetrachloride and tetralin, which dissolve polystyrenes very readily. These are solvents with a tendency to form solvates with the aromatic radicals of the polystyrene molecules as well as with their aliphatic chains. Other solvents, as for instance butyl-acetate or methyl-ethyl-ketone do not form solvates with the aliphatic chains. Cyclohexane and decaline, on the other hand, show affinity to the aliphatic chains only, and do not form solvates with organic radicals. In solvents

FIG. 2.

of this kind, which only partially solvate the polystyrenes, these substances are soluble to a much lesser degree than in the first mentioned solvents. We have investigated the swelling of the polystyrenes with limited swelling capacity in all these solvents. We found a much stronger swelling in "good" solvents; the swelling was nearly independent of the nature of the solvent, provided that it belonged to this group. In solvents of the second kind, the swelling was much weaker, especially in cyclohexane, which forms solvates with aliphatic chains only. In comparing the swelling of different polystyrene preparations with variable concentrations of divinylbenzene, in different solvents, we found that all of them behaved in the same way. This is shown by Table III. and Fig. 2.

TABLE III.—INCREASE IN VOLUME  $\frac{v_2 - v_1}{v_1}$  BY SWELLING OF "MIXED" POLYMERS OF VARIABLE COMPOSITION IN DIFFERENT SOLVENTS.

Mols. Styrene per Mol. Divinylbenzene.	CS <sub>2</sub> .	C <sub>6</sub> H <sub>6</sub> .	CCl <sub>4</sub> .	Tetralin.	Butyl-acetate.	Methyl ethyl ketone.	Decaline.	Cyclo-hexane.
1,000 I. . .	8.0	8.6	8.5	8.3	5.5	3.4	2.5	1.2
1,000 II. . .	—	8.9	—	10.0	—	—	2.9	1.7
5,000 . . .	10.7	14.1	16.0	11.4	9.1	4.6	6.2	2.8
10,000 I. . .	20.3	19.6	20.6	21.6	11.6	6.6	11.1	2.9
10,000 II. . .	19.0	18.8	20.0	18.0	9.8	7.4	8.6	2.3

<sup>9</sup> H. Staudinger and W. Heuer, *Zeit. physikal. Chemie.*, 1934, 171A, 129.

We also showed in a previous paper that the specific viscosity of a polystyrene in "good" solvents is independent of the nature of the solvent. In "bad" solvents we found values of  $\eta_{sp}/c$  which were generally much smaller. The numbers are given in Table IV. for two different polystyrenes.

TABLE IV.— $\eta_{sp}/c$  VALUES FOR TWO POLYSTYRENES IN DIFFERENT SOLVENTS ( $c = 0.02$  mols. per litre = 0.2 per cent.)

Polystyrene. Mol. Weight.	CS <sub>2</sub> .	C <sub>6</sub> H <sub>6</sub> .	CCl <sub>4</sub> .	Tetralin.	Butyl- acetate.	Methyl ethyl ketone.	Decaline.	Cyclo- hexane.
60,000 .	9.1	10.9	9.3	9.8	6.0	5.1	5.8	1.8
140,000 .	23.9	27.9	25.4	26.5	14.9	9.4	9.6	insoluble

A comparison between Tables III. and IV. shows that the viscosity of polystyrenes in solution is closely connected with their swelling capacity. The explanation is that swelling capacity, solubility and viscosity all ultimately depend on the strength of solvation of the molecules of polystyrene by the corresponding solvent.

### Soluble and Insoluble Caoutchouc ; Synthetic Caoutchouc.

It is well known that the ordinary, soluble and unlimitedly swelling caoutchouc, when stocked for a long time, is transformed into an insoluble caoutchouc with limited swelling capacity. It can be made soluble again by mastication. It was therefore supposed that the transformation of the soluble caoutchouc into the insoluble one was a reversible process.<sup>10</sup> Subsequent investigations revealed, however, that this transformation of the " $\alpha$ -caoutchouc" into the " $\beta$ -caoutchouc" occurs only in presence of oxygen<sup>11</sup> and the long chain-molecules of the  $\alpha$ -form are converted into three-dimensional molecules of the  $\beta$ -form by oxygen-links between the chains. By masticating the insoluble caoutchouc, the three-dimensional molecules are broken-up;<sup>12</sup> at the same time, the chains are shortened by oxidation. The "regenerated" soluble caoutchouc is therefore a highly degraded product; the order of polymerisation of its molecules is not greater than 300-500, as against 1000-2000 of the original product. The transformation of the soluble caoutchouc into the  $\beta$ -modification is thus not a reversible colloidal process, but an irreversible change in the chemical structure of the macromolecules.

The polymerisation of butadiene leads sometimes to soluble, sometimes to insoluble products. The soluble synthetic caoutchouc is composed of single thread-shaped molecules. Our experience with polystyrenes led us to assume that the insoluble synthetic product is distinguished from the soluble one by the existence of links between the single threads. The more complicated molecular structure of the synthetic isoprene caoutchouc as compared with the natural product has

<sup>10</sup> P. Bary and E. A. Hauser, *Kautschuk*, 1928, 97.

<sup>12</sup> H. Staudinger and W. Heuer, *Ber. Dt. Chem. Ges.*, 1934, 67, 1159.

been established previously by experiments of degradation with ozone. The butadiene-caoutchouc certainly has a very irregular structure, because its ozonisation yields only a very small quantity of succinic acid (which could be expected to be formed in great quantities if the structure were regular). Furthermore, the catalytic reduction of this kind of synthetic rubber leads to easily soluble high-molecular paraffins. Since high molecular normal paraffins are insoluble or only slightly soluble, these reduction-products must have molecules with side-chains.<sup>13</sup> This points to the existence of branched chains in the polymeric butadiene itself. We may suggest the following diagrammatic formula of this synthetic product : <sup>14</sup>

Thus, in the case of caoutchouc, also the difference between the modification with limited and the one with unlimited swelling capacity is based also on different molecular structures.

### Biological Significance of these Experiments.

The above-described experiments permit the general conclusion that colloids with limited swelling capacity are composed of long thread-molecules, linked together by some kind of "bridges" to three-dimensional molecules. The longer the threads and the smaller the number of links the higher the swelling capacity of the molecular colloid. The number of atoms in the links is exceedingly small as compared with their number in the chains; despite this small proportion, the existence of the links changes completely the physical properties of the colloid, especially in regard to its solubility. The only substances liable to change their physical properties (and sometimes their chemical behaviour as well) by such minute changes in their structure are those of extremely high molecular weight.<sup>15</sup> All changes in the properties of organic substances are based on changes in their molecules. If a substance has molecules of a small molecular weight, every atom or group added to it will appreciably change its composition, and the addition can be detected by ordinary chemical analysis. The position becomes different, where highly-polymeric molecules are concerned. A very slight change in the structure of the macro-molecules can lead to a very important change in properties, as we have seen in the cases discussed above. The corresponding changes in the composition of the

<sup>18</sup> The influence of side-chains on solubility is discussed by H. Staudinger and E. O. Leupold, *Helv. chim. acta*, 1931, **18**, 224.

<sup>14</sup> H. Staudinger and W. Heuer, *Ber. Dt. Chem. Ges.*, 1934, **67**, 1172.

<sup>15</sup> Compare for instance the completely different behaviour of  $\alpha$ - and  $\gamma$ -polyoxymethylenes, H. Staudinger and collaborators, *Liebigs Annalen*, 1929, 474, 159; and H. Staudinger, *Die Bedeutung der Erforschung hochpolymerer Stoffe für die Biologie*, in *Zangger-Festschrift*, Rascher, Zürich, 1934.

macro-molecule may be so small that they escape detection by analytical methods. Only a happy chance permits us to recognise the existing differences in structure of the macro-molecules as in the case of polystyrene, where we are able to prepare the corresponding polymeric substances synthetically.

Many substances of great biological importance are of highly-polymeric structure—proteins being the most important example. We may expect that in these cases, too, a minute change of composition may lead to important changes in physical properties. A slight change in the composition, hardly detectable analytically, may, for instance, convert a soluble protein into an insoluble one. The experiments on polystyrenes, which form the main subject of this paper, may therefore acquire some biological interest, as analogies to biologically important reactions.

### GENERAL DISCUSSION.

**Mr. N. J. L. Megson** (*Teddington*) said: The effect of small quantities of divinylbenzene in bringing about insolubility of polystyrene, reported by Professor Staudinger, recalls the hardening of soluble "Novolak" resins by small proportions of formaldehyde. This hardening may be attributed to cross-linking of phenol-methylene chains by methylene groups (involving in this case, elimination of water). Before final insolubility and infusibility are attained, the resin passes through the so-called "B" stage, when the material swells in acetone, but is insoluble.

**Dr. E. Bergmann** (*Rehoboth*) said: The paper mentions that the unsaturated di-indene is converted by heating into a saturated isomer. Now, the usual reaction of unsaturated dimers, *e.g.* in the case of dimeric  $\alpha$ -methyl-styrene

is impossible in the case of di-indene on stereochemical grounds, the expected substance

hardly being stable. Is not the so-called saturated dimer identical with truxene? The question seems a plain organic one, but the above cyclisation reaction may be of importance, since it provides one of the possible chain-breaking mechanisms.

**Professor H. I. Waterman** (*Delft*) said: Speaking also in the name of J. C. Vlугter, we direct attention to Table V. of G. S. Whitby's paper, in which a number of atoms of bromine added after a period of one day is

1.10, after three days 1.82, and after four days 2.00. We do not agree with the conclusion that "had a longer period of absorption than twenty-four hours in analogous experiments been given the bromine addition of all samples would have been equivalent to two atoms per mole."

Our experience is that the bromine addition values generally do not give good results for polymerised unsaturated hydrocarbons of higher molecular weight. In this connection, we ask the opinion of Professor Staudinger because it was a paper of Staudinger and Steinhöfer which was cited in Whitby's work.

Staudinger found that the addition of very small quantities of divinyl benzene caused the formation of insoluble styrene polymers. We think that this is a very important experiment which may find application in industrial work. On the other hand, this and analogous experiments prove that the viscosity of such systems of styrene polymers will depend very much on the presence of impurity, even though only traces of impurities are present.

Professor H. Staudinger (Freiburg i. Br.) said: Mr. Whitby states that the polystyrenes contain double bonds at the end of the molecule, the number of which can be determined by bromine titration. In this way he claims to be able to estimate the molecular weight of polystyrene by an end group determination. Mr. Waterman has asked me whether or not corresponding observations have been made at the Freiburg laboratories, since Mr. Whitby quotes the work of A. Steinhöfer<sup>16</sup> as a proof for his point of view. Dr. Waterman is of the opinion that in the case of high molecular unsaturated compounds the addition of bromine proceeds only very slowly, and the amount of added bromine cannot be determined accurately enough. The observations of A. Steinhöfer and of M. Brunner<sup>17</sup> agree absolutely with this conception. With increasing time of reaction the bromine addition increases more and more, and a marked end point of the reaction, particularly in the case of higher molecular weight compounds, cannot be noticed. However, one can determine the amount of bromine which is taken up by substitution through the determination of the amount of eliminated hydrogen bromide. Even in the case of hemicolloidal polystyrenes the molecular weights from the bromine titration method do not agree with the values obtained by the cryscopical and viscosimetric methods. In other words, it is not possible to decide definitely whether or not the hemicolloidal polystyrenes bear a double bond at the end of the thread molecule, and take up one bromine molecule per double bond.

Professor K. H. Meyer (Genève) said: If Professor Staudinger says that the variation of the solubility of natural substances of apparently identical chemical composition is to be generally explained by their different micellar structure rather than by a different molecular constitution, he will remember that we advanced the explanation by cross linkings, as early as 1928 and 1929.<sup>18</sup> We discussed in a general way the effect of cross linkings on the physical behaviour, of both synthetic and natural material. The theory now generally adopted, that the physical effect of vulcanisation is due to the chemical *Vernetzung* (formation of a three-dimensional network) was a result of these considerations.<sup>1</sup>

Very often natural products are rendered soluble by some chemical treatment or by boiling (e.g., collagen-gelatin). The nature of the chemical cross linkings cannot be established by analysing and comparing the soluble and the insoluble product, as Staudinger emphasises, in view of the minute quantities of these bindings. But their nature can be revealed by kinetic investigations. The temperature coefficient of the reaction (i.e., the transformation of the insoluble into the soluble product) and the

<sup>16</sup> H. Staudinger and A. Steinhöfer, *Liebigs Annalen*, 1935, 517, 42.

influence of added chemicals can elucidate the nature of the reaction and of the bridge, which is split up (e.g., the bucking of cellulose, the transformation of collagen into gelatin, of insoluble into soluble starch).

Not only chemical homeopolar bridges, but also bridges of dipole-forces or other weaker forces, may be the cause of the phenomenon of limited swelling. If, for instance, some OH or C=O groups are attached to a high molecular hydrocarbon soluble in benzene, they combine with other similar groups of other macromolecules to form quadrupoles, and these cross linkings are not split up by apolar solvents. The following is a very characteristic example: Natural rubber is imperfectly soluble in benzene. The insoluble part (so-called "gelcautchouc") is rendered soluble in the cold by addition of some butyl alcohol, a fact well known in the rubber industry. The explanation is, that the quadrupole linkings which are due to the presence of very few oxygen or nitrogen atoms in the molecule and which form the network, are solvated and split up by the polar solvent.

Dr. F. C. Wood (*Manchester*) said: The effect described with polystyrene and a small quantity of divinyl benzene has an exact parallel in cellulose chemistry where a small quantity of formaldehyde fixed to regenerated cellulose (as methylene ether) converts a swellable fibre, soluble in cuprammonium hydroxide, into a non-swellable fibre insoluble in this solvent.

The explanation of this was suggested to me many years ago by Mr. H. J. P. Venn, and the same explanation was published by Meunier and Guyot in 1929 on similar lines to those now used by Professor Staudinger.

Professor H. Staudinger (*Freiburg i Br.*) said: I am obliged for the mention of further examples of limited swelling colloids, which, it is justifiable to assume, are built up of thread molecules linked by chemical cross linkages so as to form three-dimensional macromolecules.<sup>19</sup> The case of the insoluble polystyrenes described in my paper differs from the above mentioned in that, in the polystyrenes, a controllable preparation of a limited-swelling colloid is possible and in that it is further possible to examine the differences in the properties of such limited-swelling colloids, firstly, as a function of the chain length of the macromolecules and, secondly, of the number of cross linkages. Thus it was possible to obtain an accurate insight into the structure of the limited swelling colloids.

In this case very small amounts of divinyl benzene can link the linear macromolecules so as to form still larger insoluble molecules. Therefore Mr. Waterman is justified in asking whether reliable conclusions about the length of the molecules can be drawn from the viscosity measurements, since indeed traces of impurities can bring about such a linking of the chain molecules. In answer to this I would like to point out, as has been done,<sup>20</sup> that a determination of the length of the molecules is possible by the viscosity measurements; that is, we determine a magnitude which is important for the characterisation of the physical properties of the substance. However, by this method we cannot ascertain whether single chain molecules or molecules of a more complicated structure, e.g. branched molecules, are present. In order to solve this question we must investigate whether the molecular weight obtained from viscosity measurements agrees with the values obtained by the osmotic method, because such an agreement will be observed only in the case where unbranched thread molecules are present.

Professor Meyer mentions that insoluble rubber (i.e. rubber in which the thread molecules are linked to each other by oxygen cross linkages, thus forming three-dimensional macromolecules) can be dissolved by merely treating it with butyl alcohol, but it should be ascertained whether the solvent was completely free from oxygen, for very small amounts of oxygen are sufficient to break down the thread molecules. This degradative effect of oxygen could render insoluble rubber soluble, since the three-

<sup>19</sup> Compare H. Staudinger, *Z. ang. Chem.*, 1929, 42, 72.

<sup>20</sup> *This vol.*, paper v.

dimensional macromolecules are changed back into thread molecules.<sup>21</sup> Of course, linkage of thread molecules may be effected not only by primary bonds but also by molecular attraction forces. Three-dimensional coordinative macromolecules of such a structure are, of course, much more unstable than three-dimensional normal macromolecules.

In regard to the swelling of high molecular weight products we must discriminate between the swelling of organised substances (e.g., natural cotton fibres) and that of substances prepared from those. The swelling of the natural cotton fibre and other natural fibres can proceed differently from that of the high molecular weight cellulose prepared from these fibres.<sup>22</sup> The reason for this is that the naturally grown substance has an internal structure different from that of the material obtained from it by further chemical treatment. But if one wishes to understand the swelling of organised substances (e.g. of natural cotton fibres) this phenomenon must be first elucidated with the substance of these fibres, the cellulose itself.

Professor G. S. Whitby (Ottawa), in reply, said: In discussing the occurrence of unsaturation in chain polymers and its extent, my concern was not exactly, as the remarks of Professors Watermann and Staudinger suggest, to deduce the molecular weight from the degree of unsaturation, but, rather, assuming the molecular weight to be reliably known by cryoscopy, to deduce the extent of unsaturation per mole. I agree that the measurement of the bromine additive capacity of highly polymerised hydrocarbon molecules is, because of experimental difficulties, by no means as exact or conclusive a method of determining the extent of unsaturation as could be wished. At the moment it is, however, the best method for which data are available. And such data considered qualitatively clearly establish the fact that the polymeric molecules *are* unsaturated and considered quantitatively suggest that the extent of the unsaturation corresponds to one double bond per molecule, irrespective of the molecular size.

After all, there would seem in the general case to be only three ways in which it is possible to resolve the indeterminateness involved in the current practice of writing the formulae of long-chain polymers with free terminal valencies (as, e.g.,  $-\text{[CHPh} \cdot \text{CH}_2\text{]}_n-$ ). The first possibility is to suppose that ring formation occurs. Against this is not only the lack of experimental evidence but the fact that, since highly polymeric products are usually mixtures representing widely different degrees of polymerisation, it is necessary to believe that a large number of rings of very different sizes (containing, say, 20, 22, 24, 26 . . . 100 . . . carbon atoms) are capable of forming with substantially the same degree of ease. The second possibility is to suppose that the terminal valencies are satisfied by "foreign" elements or groups, derived, not from the polymerisant, but from the medium. Staudinger has found such groups to be present when formaldehyde is polymerised in the presence of water. In this case, however, not a true polymerisation process but a condensation polymerisation process (to use the terms employed by Professor Staudinger in his discussion of Dr. Carothers' paper) is involved, each molecule of formaldehyde or at least one molecule per chain reacting as  $\text{OH} \cdot \text{CH}_2 \cdot \text{OH}$ .<sup>23</sup> No evidence has been secured, despite a search for it, of the occurrence of "foreign" end groups in the products of true polymerisation processes, and, indeed, since in such cases pure chemical substances polymerise or can be caused to polymerise without the intervention of chemical reagents or a reaction medium, it seems *a priori* unlikely that foreign end groups can enter in. There remains then the third possibility, *vis.* the occurrence of a terminal double bond. Since this has not the *a priori* unlikelihood of the first two possibilities, it must be given serious consideration, and, as I tried to indicate, is not in fact without experimental support.

# ALDEHYDE PHENOLIC CONDENSATIONS FROM A CHEMICAL STANDPOINT.

BY N. J. L. MEGSON.

*Received 2nd August, 1935.*

Both crystalline and resinous products resulting through condensations of formaldehyde with phenols have been known for many years, and it is common knowledge to what extent phenolic resinoids have dominated the field of synthetic resins since their first commercial exploitation in 1908 by Dr. L. H. Baekeland and others. It is nevertheless true, that of all resins manufactured industrially to-day, least is understood of the structure of these phenolic materials. This position is brought about, partly, because the immediate requirements of industry have been satisfied without the necessity of a great deal of fundamental research, and, partly, because of the difficulties encountered by early investigators in the elucidation of substances as intractable as hardened resinoid.

It is only since 1925, when Baekeland and Bender published their well-known paper,<sup>1</sup> which contained a comprehensive summary of previous work, that systematic study has been made of the problem. Until that date, assignment of structure to account for known properties was largely guesswork. The knowledge that acidic condensations of phenols with formaldehyde generally led to compounds of dihydroxydiaryl-methane type, and that alkaline condensations produced phenolic alcohols, was linked with the facts that acidic condensations frequently led to permanently fusible and soluble resins (Novolaks), and that condensations under alkaline conditions generally led to heat-hardening resins ("Bakelite" type). Early speculations by Raschig<sup>2</sup> suggested that Novolaks were mixtures of dihydroxydiarylmethanes with phenolic alcohols and free phenol, the isomerism possible in these compounds being responsible for the resinous state, and rendering difficult isolation of individual constituents.

It is intended in the present communication to deal with certain aspects of Novolaks as revealed by chemical examination of their constituents. Such resins may be regarded as intermediates in the production of resinoids, and knowledge of their structure would assist substantially the elucidation of many problems associated with the more complex material.

Despite the difficulty of disproving the conclusions of Baekeland and Bender, who regarded Novolaks as best represented by a phenoxy-hydroxyphenylmethane structure, present views incline to Scheme I., which satisfactorily explains the formation of the fusible, soluble type of resin.

<sup>1</sup> L. H. Baekeland and H. L. Bender, *Ind. Eng. Chem.*, 1925, 17, 225.

<sup>2</sup> Raschig, *Z. angew. Chem.*, 1912, 25, 1945.

## SCHEME I.

1.  $R.OH + CH_2O \rightarrow HO.R'.CH_2OH$  (phenolic alcohols)
- 1a.  $R.OH + xCH_2O \rightarrow HO.R^x.(CH_2OH)_x$  (phenolic polyalcohols).
2.  $HO.R'.CH_2OH + R.OH \rightarrow HO.R'.CH_2.R'.OH + H_2O$   
(dihydroxydiarylmethanes).
3.  $HO.R'.CH_2.R'.OH + CH_2O \rightarrow HO.R'.CH_2.R''.(OH).CH_2OH$   
(alcohol of dihydroxydiarylmethanes).
4.  $HO.R'.CH_2.R''.(OH).CH_2OH + R.OH \rightarrow$   
 $HO.R'.CH_2.R''.(OH).CH_2.R'.OH$  (trinuclear compound).
5. In general :—  
 $x.R.OH + (x-1)CH_2O \rightarrow HO.R'.CH_2.(R''(OH).CH_2)_{x-1}.R'.OH$   
(polynuclear chain compound) +  $(x-1)H_2O$

Essentially, the process consists of the entry of formaldehyde into phenolic nuclei to form alcohols, followed by condensation with more phenol. The polynuclear chain compounds cannot be called polymerides, since their production involves elimination of water, and they are not reversible. It is not considered that a Novolak can be represented by any one particular polynuclear compound; it will be made up of a complex mixture of such compounds, and possibly their alcohols, and its molecular weight will be the mean value of the molecular weights of its constituents. This complexity is increased by the presence of numerous isomerides of the polynuclear type of substance,<sup>5</sup> the only phenols in which this type of complexity does not arise being certain of those which contain but two or less *o-p*-positions available for substitution (*e.g.* *p*-cresol, *m*-2-xenol). Such a complex mixture will form a system in which crystallisation of individuals will be difficult, and hence the resinous state will be the stable one. Raschig,<sup>3</sup> and later Blumfeldt,<sup>4</sup> came close to the truth in their speculations, which were, however, made at a time when reliable experimental evidence was not available.

The experimental evidence on which the adoption of Scheme I. is based, can be summarised as follows :—

(a) The isolation of crystalline compounds of phenolic alcohol,<sup>5</sup> dihydroxydiarylmethane,<sup>6,7,8</sup> and related types from acidic resinous condensations.

(b) The practical realisation of step 2, involving condensation of phenols with phenolic alcohols to give dihydroxydiarylmethanes.<sup>6,7,9</sup>

(c) The preparation of polynuclear compounds and their alcohols from *p*-cresol-formaldehyde condensations (Koebner<sup>9</sup>).

(d) Molecular weights, which were shown by Koebner to increase with increased proportion of formaldehyde, whereby longer chains would be expected because the available methylene groups approached the phenolic nuclei in number. Koebner obtained molecular weights for phenol Novolaks as low as 200, confirming Raschig's idea that the resins may consist of comparatively simple mixtures of isomerides.

(e) Estimation by Pollak and Riesenfeld<sup>10</sup> of substances eliminated during resin formation (*e.g.*, uncombined phenol, formaldehyde and

water of condensation), followed by molecular weight determinations. These workers concluded that Novolaks consisted of seven phenolic nuclei united by six methylene groups. Experimental conditions appear to affect this result since repetition of the work by the author yielded resins of appreciably lower molecular weights (350-500 against 522).

(f) Ultimate analyses of resins, which although of little value for assigning actual formulæ, serve as a check on the type of molecular structure involved.<sup>11</sup>

(g) Examination of derivatives of resins, such as acetyl, benzoyl and benzyl.<sup>11</sup>

(h) Absorption spectra and refraction experiments<sup>12</sup> which imply the persistence of phenyl-methylene chain compounds in resinoids produced under alkaline conditions, and presumably therefore their presence in Novolaks.

(i) Alkaline hydrolysis of resins under pressure to give phenolic homologues.<sup>13</sup>

Further evidence is now presented in support of Scheme I, based on the nature and yields of products obtained by vacuum distillation and pyrolytic decomposition of Novolaks. An implication from Koeber's molecular weight determinations, that yields of lower condensation products decrease with increased formaldehyde concentration, is confirmed by direct isolation of certain compounds.

It is possible to predict what products would be obtained from the degradation of Novolaks, on the assumption that the latter may be regarded as extended dihydroxydiarylmethanes. Consider a constituent of a Novolak prepared from phenol, in which random *o-p*-substitution is assumed:—

Decomposition of this compound by heat may cause splitting in various ways. If rupture takes place at A, phenol will be broken off from the end of the molecule, but if it occurs at B or C, *o*- or *p*-cresol should result. If breaking takes place at A and D simultaneously, *m*-2-xenol should be produced, and similarly splitting between E and F should yield *m*-4-xenol. Another case arises, should decomposition occur simultaneously at B and E; a dihydroxydiphenylmethane would be formed, which according to its stability might distil as such, or decompose to give phenols, or lose water between hydroxyl groups to give volatile xanthene, which is the only form in which 2 : 2'-dihydroxydiphenyl-

methane exists. If, furthermore, cross-linking of long chains be assumed possible, mesitol could theoretically be produced.

The substances which would be anticipated from other phenolic condensations can be deduced in a similar manner, such substances depending generally on the *o-p*-rule of substitution which limits the number and type of phenols and xanthenes possible.

It should be noted, that an analogous structure based on the phenoxy hypothesis of Baekeland and Bender, would be likely to yield phenols and xanthenes only if, as a result of heating, immediate transformation to the phenolic type of chain, occurred.

The isolation of various phenols and xanthenes from the degradation products of Novolaks, in agreement with the above deductions, has now been achieved, and information thereby becomes available as to nuclear positions occupied by methylene groups.

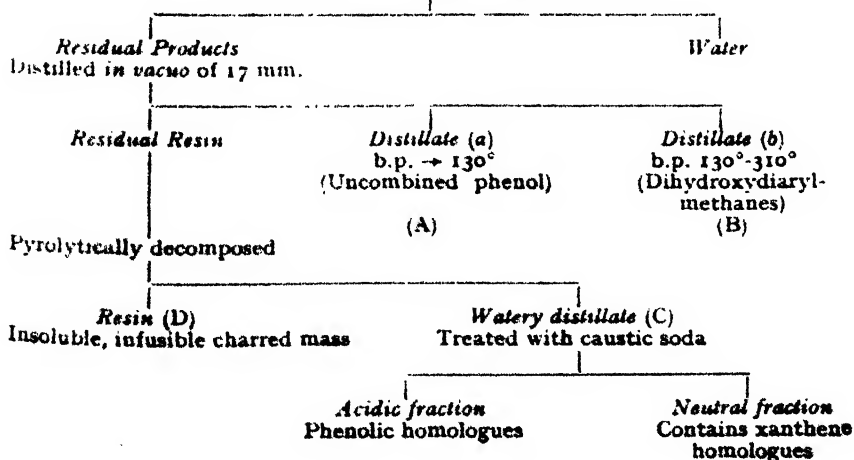

### General Experimental Method.

The method by which condensations were examined is given in Scheme II. Condensations were carried out with phenols and aqueous formaldehyde in presence of acid until permanent turbidity at 100° first appeared. The mixture was cooled, the supernatant liquid decanted, and the bottom layer washed repeatedly with hot water to remove catalyst, excess formaldehyde, and water-soluble uncombined phenols. The resulting resin was heated to remove water, and a little steam-distilled phenol, and was then distilled under a pressure of about 15-17 mm. The first distillate was almost entirely uncombined phenol, (A), and the second was a nearly colourless glass, consisting chiefly of dihydroxydiarylmethane isomerides (B). Immediately signs of decomposition appeared, distillation was stopped and the residual resin was decomposed by heating strongly (up to 450° in the resin) at normal pressures, until all distillation ceased. The watery distillate (C), which was accompanied by inflammable vapours whose nature was not determined, contained acidic and neutral materials, separable by caustic soda. The acidic fraction was a mixture of phenols, made up of the original phenol with certain of its methyl homologues, and the neutral fraction contained substances of xanthene type.

#### SCHEME II.

##### CONDENSATION PRODUCT.

Top layer decanted. Resin washed several times with hot water. Distilled at normal pressure.

The products of condensation, after preliminary distillation of water, were invariably resinous in character, and despite the high percentage of dihydroxydiarylmethanes frequently present in them, deposited crystals only very slowly. The amount of coke-like residue (D) left after destructive distillation, increased in yield with increase of formaldehyde.

Examination of condensation products derived from phenol, *o*-, *m*- and *p*-cresols and *m*-5-xyleneol has been carried out. A more detailed publication of the results discussed below, will be made in a later communication.

Phenol should theoretically produce three dihydroxydiphenylmethanes,

of which II. and III. are known and have been isolated from resinous condensations. There appears, from previous work,<sup>4</sup> to be a connection between time of condensation and yield of III., the latter apparently functioning more truly than does II. as an intermediate in resin formation. Vacuum distillation of phenol resin has now given high yields of mixed II. and III. (for low proportions of formaldehyde), with the former slightly preponderating. With increase of formaldehyde through the proportions 0.5, 1.0, 1.5 and 2.0 mols. per mol. of phenol, the yields of fraction (B) were 45 g., 26 g., 20 g. and 0 g. respectively. IV. is not known, but exists in a dehydrated form as xanthene, V.

Xanthene has never been identified in phenol resins, which are invariably completely soluble in caustic soda.

Consideration of formula I. has already shown that degradation of phenol resins may yield phenol, *o*- and *p*-cresols, *m*-2- and *m*-4-xyleneols and mesitol, in addition to xanthene. The author has been able to identify only phenol, *o*- and *p*-cresols in the acid fraction of the decomposition products (C), which increased through 12.5 g., 18 g., (17 g.), and 35 g. with increase of formaldehyde through 0.5, 1.0, 1.5 and 2.0 molecules respectively. The small yield of *p*-cresol, compared with that of *o*-cresol, suggests that *p*-substitution is of less frequent occurrence than *o*-substitution, but the observed preponderance of II. over III. contradicts this conclusion. It is possible, either that decomposition takes place more readily at *o*- than at *p*-linkages, or that the resin itself contains a high proportion of *o*-linkages, brought about by continued condensation of III. in preference to II.

The neutral decomposition products apparently contained xanthene and methyl homologues. The production of these homologues is understandable if splitting of the long chain compound I. takes place at A and G simultaneously, with subsequent or coincident elimination of water between hydroxyl groups.

Phenol resins were more difficult to deal with than others examined, owing to their tendency to pass over to the "gel" stage during vacuum distillation. This tendency is probably due to ready formation of cross-linked compounds, which are not produced so easily in higher phenols owing to steric hindrance effects of methyl substituents.

*o*-Cresol should form three dihydroxyditolylmethanes:

VII.

VIII.

IX.

Only VII. is known and has been isolated from *o*-cresol-formaldehyde condensations.<sup>6</sup> By elimination of water between hydroxyl groups, VIII. should yield 4:5-dimethylxanthene. The phenols produced by pyrolysis should be, *o*-cresol, *m*-2- and *m*-4-xyenols and mesitol.

The only crystalline condensation product obtained from this phenol was VI. in high yield (38 g. from 108 g. of *o*-cresol). No indication of VII. or VIII. was found, and the resin remaining after vacuum distillation was so small (8 g.), that pyrolysis was not proceeded with. Nearly identical results were obtained when formaldehyde was increased from 0.5 mols. to 1.0 mols. It appears that substitution in this condensation takes place almost entirely *p*- to the hydroxyl group, an observation which may be connected with the known difficulty of producing *o*-cresol resins possessing high melting-point, or rapid heat-hardening characteristics.

*m*-Cresol, because of its asymmetry, theoretically forms a more complicated series of condensation products than any other of the methyl phenols; there are, for example, no less than six possible dihydroxyditolylmethanes:

X.

XI.

XII.

XIII.

XIV.

XV.

Of these only two have previously been reported, m.p. 161°<sup>6</sup> and m.p. 113°<sup>14</sup> respectively, both of which were separated from cresol-formaldehyde condensations. The author has now isolated two more *isomerides*, m.p. 99° and m.p. 134°, from the products of vacuum distillation (B), but the orientation of none of these compounds is known.

The substance melting at 99° was crystallised from light petroleum, b.p. 60/80°, in microscopic needles. (Found: C 79.1 per cent., H 7.13 per cent.;  $C_{18}H_{18}O_2$  requires C 78.9 per cent., H 7.02 per cent.) *Tetra-bromo-derivative*: Found: Br 57.7 per cent.;  $C_{18}H_{18}O_2Br_4$  requires Br 58.8 per cent. The isomeride melting at 134° crystallised from benzene-petroleum in rosettes of spears (Found: C 78.9 per cent., H 6.88 per cent.;  $C_{18}H_{18}O_2$  requires C 78.9 per cent., H 7.02 per cent.). (All above are microanalyses.)

The yields of fraction (B) constituted 35 per cent., 24 per cent., 18 per cent. and 11 per cent. respectively, of the dry resin, for 0.5, 1.0, 1.5 and 2.0 molecular proportions of formaldehyde. Uncombined *m*-cresol (A) decreased through the yields; 32 per cent., 16 per cent., 12 per cent., — per cent.

<sup>14</sup> W. C. Harden and E. E. Reid, *J. Am. Chem. Soc.*, 1932, **54**, 4325.

By elimination of water between the hydroxyl groups of XII., XIII. and XIV., three dimethylxanthenes should be formed.

Pyrolysis of *m*-cresol resin has given a mixture of xanthenes, in which XV., m.p. 199°-200°<sup>15</sup> has been identified, together with an unknown impure xanthene, m.p. 152°-154°, probably XVI. or XVII.

The phenols obtainable by pyrolysis should be *m*-cresol, *o*:3-, *o*:4- and *p*-xylenols,  $\psi$ -cumenol, *vic*- $\psi$ -cumenol, *as*-hemellitenol and *iso*-durenol. It has been possible by fractional distillation of the phenols from (C) to isolate *o*:4-xylenol, *p*-xylenol and  $\psi$ -cumenol. The fact that no *o*:3-xylenol was detected is considered as due to the method of separation of phenols, rather than to its absence, since the groupings contained in XVI. and XVII., one of which has been isolated, should yield this phenol on decomposition. The positive existence of both *o*- and *p*-linkages, shown by the phenols identified, implies high complexity of products in *m*-cresol resins.

It cannot be inferred from the isolation of xanthenes from this and other pyrolytic processes, that these compounds exist as such in resins, but only that *o*-*o'*-dihydroxy groupings are present. No free xanthenes were ever detected in fraction (B), where they would distil if present in the free state.

*p*-Cresol, by virtue of its symmetry and possession of only two positions open to substitution, forms an extremely simple series of condensation products, there being only one possible isomeride for any given length of chain. The smallest possible chain compounds are XVIII. and XIX., both of which have previously been identified in resinous condensations.<sup>8</sup> Both have now been isolated from the products of vacuum distillation, in agreement with Koebner's observations.

108 g. of *p*-cresol with 45 g. of formaldehyde yielded 33 g. of free *p*-cresol (A), 26 g. of (B), 21 g. of decomposition products (C) and 21 g. of residue (D).

The phenols theoretically derivable by pyrolysis are *p*-cresol, *m*-4-xylenol and mesitol. None higher than *p*-cresol has been detected with certainty although higher boiling unidentified phenols have been noticed in small quantity. The neutral fraction has yielded 2:7-dimethylxanthene (XX)<sup>16</sup>:

<sup>15</sup> Gladstone and Tribe, *J.C.S.*, 1882, 41, 11.

<sup>16</sup> M. R. Fosse, *C. rend.*, 1903, 136, 1006.

The supposition that xanthenes are formed during pyrolysis of resins by elimination of water between *o-o'*-hydroxy groups, is supported by an observation that simple heating of XVIII. is sufficient to remove water and to give a distillate consisting chiefly of XX. Furthermore, destructive distillation of the three-ring compound XIX., gave the same xanthene, together with phenolic material containing *p*-cresol. This latter experiment closely imitates the conditions existing during pyrolysis of resins.

Owing undoubtedly to its simple structure, Novolak from *p*-cresol exhibits a greater tendency to crystallisation than other phenolic resins. During previous work,<sup>6</sup> in which condensations were carried out with para-formaldehyde in alcoholic solution, most phenols gave resinous solutions which merely became more viscous with time of condensation. The numerous isomerides formed, not necessarily of great length or of high melting-points, presumably formed a highly complex system soluble in alcohol, whereby precipitation of individual compounds was inhibited. During *p*-cresol experiments, a white substance was deposited, which increased considerably with time; it probably consisted of comparatively few long chain compounds of high melting-points, which were unable to form such a soluble system, and hence crystallisation occurred.

*m*-5-Xylenol resembles phenol in the number of condensation products it yields. The three possible dihydroxydixylylmethanes have all been isolated from resinous condensations.<sup>7</sup> They have not been individually characterised with certainty, although there is some evidence that XXI. represents the compound of highest melting-point. All these compounds have now been identified in the products of vacuum distillation:

For the proportions of formaldehyde examined the variations in fractions (A), (B), (C) and (D) closely resembled those from other phenols.

The higher phenols anticipated by pyrolysis are *sym*-hemellitenol, *iso-ψ*-cumenol, durenol, prehnitenol, and pentamethylphenol. Of these there have been identified by fractional crystallisation *iso-ψ*-cumenol and durenol. The formation of these two substances shows that substitution has proceeded almost entirely in the *o*-positions, a surprising observation in view of the fact that, under alkaline conditions, *m*-5-xylenol gives a monoalcohol, which Auwers<sup>17</sup> has shown to be *p*-hydroxyhemellityl alcohol. It is possible, however, that under acidic conditions *p*- and *o*-alcohols are formed together, that the *p*-alcohol immediately combines with xylenol to give XXI., and that the main condensation proceeds through the *o*-alcohol (*cf.* phenol condensation). Alternatively it is possible that the *o*-linkage is more easily ruptured by heat than the *p*-linkage.

Steric hindrance effects probably oppose substitution of this xylenol in all three available positions, and therefore the tendency will be towards long chain compounds with little cross linking. Oil-solubility should thereby be favoured.

<sup>17</sup> K. von Auwers, *Ann.*, 1906, 344, 271.

Only one xanthene would be expected from pyrolysis, 1:3:6:8-tetramethylxanthene XXIV, being derivable from the structure contained in XXIII.

This compound has been identified, crystallising from acetone in small glistening plates, m.p. 198°-200°. (Found: C 85.4 per cent.; H 7.85 per cent.;  $C_{14}H_{18}O$  requires C 85.7 per cent., H 7.57 per cent.) At the same time a minute yield of a second material was isolated insoluble in caustic soda, which sublimes above 275°. It has been tentatively assigned the formula of a hexamethylxanthene (XXV.). The type of decomposition required to produce this compound has already been referred to under phenol, and there seems no reason to doubt its possibility in resins from other phenols.

**Alkaline Condensations.**—It is of interest that similar pyrolyses carried out with the products from alkaline phenolic condensations have yielded similar results. A commercial heat-hardening resin derived from *m*-cresol, on pyrolysis gave not only *m*-cresol, but higher homologues in which *o*-4-xylene has been detected. It is concluded that the basic structures of resins derived under acidic and alkaline conditions are closely related.

Although the results presented here assist elucidation of complex phenolic condensations, they yet leave numerous questions open to investigation. It is desirable, for example, not only to characterise the structure of the dihydroxydiarylmethanes produced, but to estimate their relative amounts, so that information will become available as to the extent to which particular isomerides influence physical properties of the resins. The isolation of polyring compounds from phenols other than *p*-cresol is a problem which may be solved by employing higher vacua during distillation of condensation products. There have been indications in the present work that fraction (B) from phenol condensations, contained constituents (less volatile than dihydroxydiphenylmethanes), which are suspected of being three ring compounds. Molecular weight determinations carried out on various resinous fractions obtained during working-up of the products would also be valuable in checking the degree of condensation achieved. Finally, a more complete examination of the products of pyrolysis, than that described above, is of evident importance.

The elucidation of these problems is a purely chemical concern. Assuming the nature of the compounds present in resins be ascertained in this way there still remains the more fundamental physico-chemical problem of determining the manner in which these substances co-exist to produce resins. In this field, valuable work has already been carried

out by von Weimarn, Tammann, Scheiber and others, whose concepts have been comprehensively discussed by Scheiber and Sändig.<sup>18</sup>

### Summary.

1. Evidence supporting the hypothesis that Novolak resins consist of complex mixtures of chain compounds of phenol-methylene type is summarised.

2. This hypothesis is supported experimentally by :

(a) Isolation of condensation products of dihydroxydiarylmethane type, which are shown to decrease in yield with increase of formaldehyde.

(b) Isolation of higher methyl homologues of phenols, and of xanthenes, by pyrolysis of resins.

In conclusion, the author thanks Professor G. T. Morgan, O.B.E., D.Sc., F.R.S., Director of Chemical Research, for permission to contribute this paper to the discussion.

*Chemical Research Laboratory,  
Teddington, Middlesex.  
July, 1935.*

### GENERAL DISCUSSION.

Professor K. H. Meyer (*Genève*) said : Hemmi and I have made the following experiments. We interrupted the alkaline condensation of phenol and formaldehyde in concentrated solution by reaction with dimethyl sulphate to etherify the phenolic hydroxyl groups, and subsequently oxidised with permanganate to convert the lateral  $-\text{CH}_2\text{OH}$  groups into carboxyl. We could isolate the following acids :

together with higher molecular compounds of the diphenylmethane series.

The acid  $\text{CH}_3\text{O} \cdot \text{C}_6\text{H}_3(\text{COOH})_2$  does not seem to be formed, which indicates

that under these conditions, either the velocity of the reaction of the di-alcohols with phenol is greater than the reactivity with formaldehyde, or else the trialcohol, when formed, reacts immediately with phenol.

Dr. E. E. Walker (*Manchester*) said : Mr. Megson has dealt successfully with the condensation products formed under acid conditions and refers at the end of his paper to those formed under alkaline conditions. The simpler mononuclear phenol alcohols which can be isolated from alkaline reaction mixtures are well known, but some years ago a substance  $\text{C}_{17}\text{H}_{16}\text{O}_6$  was isolated from such a reaction mixture in the laboratories of Imperial Chemical Industries Limited. This was found to be a derivative of 4 : 4'-dihydroxydiphenylmethane and almost certainly possesses the constitution :

<sup>18</sup> J. Scheiber and K. Sändig, *Artificial Resins*, translated by E. Fyleman, London, 1931.

The manner in which a high molecular weight substance can be built up from this by condensation with free phenol and less highly substituted phenol alcohols is obvious.

Similarly it has been found that the constitution of the crystalline substance isolated from alkaline *o*-cresol formaldehyde condensation products is :

These observations seem to indicate that the first condensation takes place in the *para*-position.

If the matter is of sufficient interest it may be possible to publish details of the isolation of these substances and the evidence for their structure.

Mr. N. J. L. Megson (*Teddington*), in reply, said : Professor Meyer's results on the oxidation of methylated phenolic products confirm the *o-p*-substitution by formaldehyde in the phenolic nucleus. It is agreed that further condensation may proceed before addition of three methylol groups to the phenol nucleus, and it may be that a certain minimum length of chain is necessary before the tendency to condensation becomes less than that of addition, and cross-linking, with formation of infusible, insoluble products, becomes possible. Against this hypothesis is the report by Dr. Walker of the isolation of tetramethylol-*p-p'*-dihydroxydiphenylmethane, which implies probable branching of chains at an early stage. The certain identification of the compound would be of considerable interest, since substances of this type have hitherto only received unreliable description in patent literature. The compound is a methylol derivative related to the dimethyloldihydroxydiarylmethanes prepared by other workers from *o*-cresol, *p*-cresol and *m*-5-xynol.<sup>19</sup>

The orientation of derivatives of diarylmethanes presents difficulties, and despite statements by investigators working with them, there is surprisingly little direct evidence giving exact positions of substituents. Thus, unless Dr. Walker possesses information other than that provided by Granger,<sup>19</sup> the constitution of the *o*-cresol-formaldehyde compound must remain speculative; it may be the 4:4', 2:4', or even 2:2'-dihydroxy-derivative of 3:3'-dimethyl-5:5'-dimethyloldiphenylmethane. The possibility of formation of three related isomerides together has already been reported for several phenols; few of them have been orientated. Hence publication by Dr. Walker of any results definitely justifying the belief that first condensation takes place in the *para*-position would clearly be of much value. The products obtained by pyrolysis of phenolic resins, which yield information on the relative positions of methylene and hydroxyl groups, have so far indicated that both *o*- and *p*-substitution occurs in *m*-cresol, but only *o*-substitution in *m*-5-xynol. More recent, unpublished, results have shown *o-p*-substitution in *o*-cresol.

There are grounds for Mr. R. H. Kienle's view that the structures contained in "Novolaks" may differ from those in hardening resins, but confirmation or otherwise of the belief cannot be obtained until the pyrolytic products from the resins have been examined in greater detail. The most that can be deduced is that certain groups, for example the phenol-methylene unit, appear to be common to both types of resin. Evidence from another type of experiment does, however, demonstrate the variations which may be caused by catalytic effects. During investigations on the production of phenolic resins from tar fractions with aqueous formaldehyde,<sup>20</sup> it was noticed that whereas pyridine readily caused

<sup>19</sup> Granger, *Ind. Eng. Chem.*, 1932, 24, 442; Koebner, *Z. angew. Chem.*, 1933 46, 251; Auwers, *Ber.*, 1907, 40, 2537.

<sup>20</sup> Holmes and Megson, *J.S.C.I.*, 1933, 52, 415T.

deposition of a lower layer of resin, ammonia, which is definitely a more rapid catalyst, only gave a resinous deposit after very prolonged condensation. In this case, solubility of resin in the tar neutral oil is apparently determined solely by the catalyst. This fact is best explained by assuming formation of two different structures as a result of catalytic action; possibly variations in oil-solubility are determined by differences in position of substitution of methylene linkages.

## THE FORMATION OF HIGH POLYMERS BY CONDENSATION BETWEEN METALLIC POLYSULPHIDES AND DIHALOGENATED HYDROCARBONS AND ETHERS.

BY J. C. PATRICK.

*Received 7th August, 1935.*

The general theory of formation of high molecular weight linear polymers by condensation between bi-functional compounds of low molecular weight to form products of large molecular mass has been so thoroughly reported in the literature that no extensive citation is believed to be advisable here.

A very thorough study of this type of reaction has been made by Carothers and his co-workers on the formation of polyesters, the reaction being of the general type:

One can, without taxing the imagination, conceive of the polymerisation of isoprene or butadiene as belonging to the same general type of phenomenon differing only in the fact that the reacting molecules are alike instead of different and that the "condensate" is one double bond per molecule. Therefore, no attempt will be made in this paper to distinguish between condensation and polymerisation.

When organic dihalides having  $\text{CH}_2\text{X}$  terminals, in which "X" denotes a halogen, are caused to react with metallic polysulphides,  $\text{MS}_x\text{M}$ , there usually results a linear polymer, of high molecular weight.

A few specific examples are as follows:

- (1)  $\text{ClCH}_2\text{Cl} + \text{M}_2\text{S}_2 \rightarrow \cdots\text{CH}_2\text{S}_2\text{CH}_2\text{S}_2\text{CH}_2\text{S}_2\cdots$
- (2)  $\text{Cl}(\text{CH}_2)_3\text{Cl} + \text{M}_2\text{S}_2 \rightarrow \cdots(\text{CH}_2)_3\text{S}_2(\text{CH}_2)_3\text{S}_2(\text{CH}_2)_3\text{S}_2\cdots$
- (3)  $\text{Cl}(\text{CH}_2)_6\text{Cl} + \text{M}_2\text{S}_2 \rightarrow \cdots(\text{CH}_2)_6\text{S}_2(\text{CH}_2)_6\text{S}_2(\text{CH}_2)_6\text{S}_2\cdots$
- (4)  $\text{ClC}_2\text{H}_4\text{OC}_2\text{H}_4\text{Cl} + \text{M}_2\text{S}_2 \rightarrow \cdots\text{C}_2\text{H}_4\text{OC}_2\text{H}_4\text{S}_2\text{C}_2\text{H}_4\text{OC}_2\text{H}_4\text{S}_2\cdots$
- (5)  $\text{ClC}_2\text{H}_4\text{OC}_2\text{H}_4\text{OC}_2\text{H}_4\text{Cl} + \text{M}_2\text{S}_2 \rightarrow \cdots\text{C}_2\text{H}_4\text{OC}_2\text{H}_4\text{OC}_2\text{H}_4\text{S}_2\text{C}_2\text{H}_4\text{OC}_2\text{H}_4\text{OC}_2\text{H}_4\text{S}_2\cdots$

Many of the linear polymers of the type given above that have been studied either have, or can be readily made to assume, highly rubber-like characteristics.

It will be noted that in the five examples given, Nos. 1, 2 and 3 involve the reaction of a simple hydrocarbon dihalide, whereas Nos. 4 and 5 show the reaction with a hydrocarbon chain containing ether linkages.

Since symmetrical dichloroethane, or ethylene dichloride may be considered typical of the first type of organic reactant, *i.e.*, the simple hydrocarbon dihalide, its reactions will be given in some detail.

If the polysulphide chosen is a solution of sodium polysulphide properly prepared and having the empirical formula  $\text{Na}_2\text{S}_4$ , it will react very readily with its equivalent weight of ethylene dichloride in the presence of a dispersing agent such as magnesium hydroxide to form a somewhat latex-like suspension of the polymer. When the suspension of particles has been washed free from the by-products of the reaction by repeated settling and decantation with water, it will coagulate to an elastic rubbery mass on acidification of the liquid.

This polymer is unique in that it shows a degree of extensibility and retractability comparable with natural rubber and also exhibits the Joule effect. According to unpublished observations of Dr. J. R. Katz, films of the polymer exhibit an X-ray fibre diagram on stretch comparable with that given by rubber under similar conditions.

Another peculiar analogy with rubber is noted when the polymer is mixed with, for example, zinc oxide and heated. At temperatures customarily used in the vulcanisation of rubber, a phenomenon superficially strikingly similar to vulcanisation takes place. The originally, somewhat plastic mix becomes firm and strongly elastic, and the effect is even more marked if a pigment of the type of carbon black, which exerts such a strongly reinforcing effect on rubber, is present.

Certain suggestions regarding the chemical structure of the ethylene polysulphide polymers will be advanced.

The reaction between ethylene dichloride and sodium tetrasulphide may be represented as :

and this process may continue as each new unit is itself bifunctional and capable of reaction at one end or the other, either with a similar unit or with either of the original reactants which happens to be in excess until either, or both, of the primary reactants is exhausted after which reaction with chain growth may continue between the already formed units with, however, rapidly diminishing frequency as the average mass of the units increases.

According to the above hypothesis the polymer would not have chlorine terminals if the polysulphide were kept always in excess, and the empirical formula of the large molecule would approach very nearly to  $\text{C}_2\text{H}_4\text{S}_4$ . This is confirmed by experimental data.

This hypothesis also postulates high molecular weight and this is also indirectly confirmed by experiment, because, while it has not been possible to determine the average molecular weight of the polymer, all attempts to determine this value have indicated that it is large.

Since there is no good reason to suppose any alteration in the structural relationships of the hydrocarbon residue in this reaction it will be assumed that the integrity of the  $-\text{CH}_2\text{CH}_2-$  radical is maintained. The arrangement of the  $\text{S}_4$  complex admits of several hypothetical groupings. One might postulate the polysulphide group as

extended into a four-sulphur chain in which each sulphur atom is linked to its neighbour or to a carbon atom by a covalent linkage such as  $\text{—C:S:S:S:C—}$ , in which each sulphur atom is of equal value as a link in the chain. Another equally valid hypothesis is to assume

S S

a configuration for the polysulphide group such as  $\text{—C:S:S:C—}$ , in which two only of the sulphur atoms are essential to the integrity of the chain and two others, possibly co-ordinately linked to the sulphur atoms in the chain might be regarded as likely to considerably modify the physical properties of the molecule. This assumed structure would lead one to suspect that the two co-ordinately linked sulphur atoms would be more easily removed than the two sulphurs each covalently linked to carbon, and that their removal, while modifying more or less extensively the properties of the molecule, would not necessarily disturb the fundamental integrity of the chain.

Experimental data show conclusively that in the molecule of  $\text{C}_2\text{H}_4\text{S}_4$ , two of the sulphur atoms are combined in a very different manner from the other two. For example, if a suspension containing one empirical molar weight of the ethylene tetrasulphide polymer is treated with a solution containing 1.2 mols of sodium hydroxide, and is heated to  $80^\circ$  or  $90^\circ$  C. with agitation for about an hour, the red polysulphide solution of the metal is formed, and when the white somewhat granular residue is washed and dried its analysis always approaches very closely to the empirical formula  $\text{C}_2\text{H}_4\text{S}_2$ . If now the disulphide derivative is again subjected to the same treatment with a fresh solution of sodium hydroxide, the polysulphide of the metal, if formed at all, will be present only in minute quantity, and when the organic derivative is removed and analysed its empirical formula is substantially unchanged.

That the tetrasulphide derivative might have consisted originally of a solid solution of two gram atoms of elementary sulphur in one mol of  $\text{C}_2\text{H}_4\text{S}_2$  is disposed of by the fact that extraction with such solvents as boiling acetone does not remove free sulphur and, even more conclusively, by sublimation of the tetrasulphide in a "molecular still" under high vacuum, in which case the empirical formula and physical properties of the sublimate correspond to  $\text{C}_2\text{H}_4\text{S}_4$ .

As might have been expected, the physical properties of the substance have undergone a change due to the removal of two sulphur atoms from the molecule.

The pale yellow tetrasulphide derivative is elastic and quite rubbery whereas after removal of the two sulphur atoms from the molecule the disulphide is a somewhat harsh granular powder, usually white in colour. This powder does not have a definite melting-point. It usually begins to soften perceptibly at around  $130^\circ$  C. and has become a viscous amber-coloured liquid at about  $180^\circ$  C., above which temperature evidences of incipient decomposition are observed. That the molecular weight is large is indicated by the fact that the polymer is practically unaffected by any organic solvent. It is not even swollen by carbon disulphide.

In view of the fact that the removal of two sulphur atoms from each unit of  $\text{C}_2\text{H}_4\text{S}_4$  caused a transition in physical properties from a rubbery elastic substance to a granular thermoplastic powder, two interesting questions present themselves. Can the two sulphur atoms be replaced with resumption of all the original rubber-like qualities?

Would considerably less than two gram atoms of sulphur per empirical molar weight of  $C_2H_4S_2$  suffice to impart rubbery characteristics?

The experimental evidence gives a complete affirmative to both questions.

If one empirical mol of  $C_2H_4S_2$  is intimately mixed with two gram atoms of sulphur especially in the presence of one or two tenths of a per cent. of an accelerator of the alkaline type (diphenyl guanidine is very suitable), and heated for twenty-four hours in an oven at  $120^\circ$  to  $130^\circ$  C. the sulphur recombines and a soft elastic mass is obtained. The same result is produced even more completely if the sulphur and the disulphide derivative are mixed on the rolls of a laboratory rubber mill with, in addition to the accelerator, about 5 per cent. by weight of zinc oxide. In this case the mass becomes plastic almost at once but will stiffen to a hard board-like consistency when cold. If now the mix is subjected to a temperature of  $145^\circ$  C. for about thirty minutes, an elastic tough substance resembling cured rubber is obtained. Here also attempts to remove sulphur by the use of selective solvents are not successful.

The answer to the second question as regards the minimum amount of sulphur competent to develop permanently rubber-like properties is easily determined by the last procedure mentioned above. When the disulphide derivative is mixed on the mill rolls with varying proportions of sulphur and the resulting mixes heated as described, it is found that sulphur in the proportion of about one gram atom to two empirical molar weights of the disulphide derivative, that is, an amount of additional sulphur which would give an empirical formula of  $C_2H_4S_{2.5}$ , suffices to confer permanent rubberiness to the full extent, but that lesser amounts of sulphur are not sufficient.

According to the hypothesis made above concerning the co-ordinate combination of sulphur, this amount of sulphur would roughly correspond to about one co-ordinately combined sulphur atom to each two units of the carbon-sulphur chain:

It is interesting to note that the addition of sulphur to form a rubbery elastic substance does not take place under the conditions described above if only one sulphur atom is present in a unit of the chain. For example, polymeric ethylene sulphide,  $-CH_2CH_2SCH_2CH_2S-$ , does not exhibit this phenomenon.

Attempts to remove more sulphur from the polymeric ethylene disulphide have been unsuccessful without complete decomposition of the molecule. However, in the presence of a suitable reducing agent the S—S bond can be broken. If one empirical molar weight of  $C_2H_4S_2$  in suspension in water is first "stripped" of two sulphur atoms with sodium hydroxide solution and, after removal of the polysulphide formed, the mol of  $C_2H_4S_2$  remaining is heated with two mols of  $Na_2S$ , in solution, to about  $90^\circ$  C. with suitable agitation for several hours, a completely water-soluble product is obtained. A reddish solution of sodium polysulphide is also formed which is found on analysis to correspond to the empirical formula  $Na_2S_3$ . Perhaps:

When acidified the aqueous solution obtained by reduction of the ethylene disulphide evolves hydrogen sulphide and eliminates sulphur due to the decomposition of the sodium disulphide. On complete

acidification it also eliminates an oily substance and on steam distillation a fair amount of ethylene mercaptan is obtained. If now one mol of this mercaptan is treated with the calculated amount of sodium hydroxide solution to form the di-mercaptide and the solution of sodium ethylene di-mercaptide is then treated with an oxidising agent such as a sodium tetrasulphide solution or a hypohalite, a substance having most of the chemical and physical properties of the ethylene disulphide polymer, from which the mercaptan was derived, is obtained.

If, instead of acidifying the mercaptide solution, obtained by reduction of  $C_2H_4S_2$  with sodium sulphide, the aqueous alkaline solution is filtered and oxidised at boiling temperature by passage of a current of air the identical parent substance is obtained, and when this polymer is treated with additional sulphur in the manner described above the elastic rubbery properties are developed in their entirety.

It is believed that the slight differences noted between the product obtained by oxidation of a pure sodium ethylene di-mercaptide, and that derived from the oxidation of the mercaptide solution obtained by first "stripping" then reducing the derivative of ethylene tetrasulphide without prior separation of the mercaptan by distillation, is due to the presence of a certain amount of sodium monosulphide in the parent polysulphide. This on reaction with  $C_2H_4Cl_2$  would lead to the formation of a certain proportion of thio-ether linkages in the molecule of the polymer:

The chain on reduction may be expected to split only between the  $-S-S-$  linkages with the result that the mercaptide solution should contain in addition to  $NaSCH_2CH_2SNa$  also a certain amount of the sodium salt of dimercapto-thioether  $NaS-C-C-S-C-C-SNa$ .

The fact that the rubbery tetrasulphide polymer can be reduced to the disulphide polymer, that this can in turn be reduced to a mixture of mercaptans of fairly well established structure which then by oxidation regenerates the polymeric disulphide, and that the disulphide then can undergo further oxidation with free sulphur to a polymeric tetrasulphide substantially identical with the original polymer, would seem to justify the following inferences:

That the fundamental recurring unit in the chain is  $-CH_2CH_2SS-$  with an occasional thioether linkage  $-CH_2CH_2SCH_2CH_2-$ .

That the terminal or end groups after acid coagulation are sulphhydryl groups  $-SH$  the same as those of the low molecular weight mercaptans from which the disulphide polymer can be synthesised by oxidation,

That the polysulphide polymers of higher sulphur rank than the disulphide polymer are co-ordination compounds with sulphur.

A tentative formula for the rubbery tetrasulphide polymer can now be constructed

The experimental data prove quite conclusively that the permanent extension-retraction elasticity, *i.e.*, rubberiness, of the ethylene derivative is dependent upon the presence of not less than a definite minimum

excess of sulphur over that required by the empirical formula  $C_2H_4S_2$ . This excess sulphur is believed to be co-ordinately combined.

As representative of the dihalides having ether linkages one may select  $\beta$ - $\beta'$  dichloroethyl ether for discussion.

When this dichloroethyl ether is reacted with sodium tetrasulphide under similar conditions to those described under ethylene dichloride, a coagulable suspension of the polymer is obtained.

This product shows the analogies with rubber to an even greater degree than is the case with the ethylene derivative.

When the same methods of investigation are applied to the polymeric ether tetrasulphide as were described in the case of the ethylene tetrasulphide, a very close parallelism can be demonstrated. There is, however, one rather remarkable difference. When the ether tetrasulphide polymer is treated with sodium hydroxide solution until no further sulphur can be removed, the latex-like suspension remaining will coagulate into a white highly elastic mass when treated with acid. This elastic polymer has by analysis the empirical formula  $OC_4H_8S_2$ . When dried and sheeted out it closely resembles natural rubber in its "liveness." This polymer undergoes a typical vulcanisation when compounded with zinc oxide or litharge and, when properly compounded with reinforcing pigment and cured, it develops a degree of elasticity and resistance to tear fully equal to rubber.

This ether disulphide polymer can be made to take up two gram-atoms of sulphur per mol of  $OC_4H_8S_2$  to reform the tetrasulphide polymer, but the addition of sulphur does not in this case enhance the rubber-like properties. The same observation applies in the case of the polymeric disulphide derivative of chloroethoxy chloroether.

The ether disulphide polymer on treatment with sodium sulphide is reduced to mercaptide from which the polymer can be regenerated by oxidation. Therefore, similar inferences regarding its structure will be made as were made in the case of the ethylene derivative.

which in the large molecule approaches closely the ratio required by the empirical formula  $OC_4H_8S_2$  given by analysis.

It is of interest that in the reaction between polysulphide solutions and  $\beta$ - $\beta'$  dichloroether about 15 to 20 per cent. of the dichloroether, depending on the type of polysulphide solution used, goes to form the cyclic compound 1-4 thioxane,

The thioxane formation is believed to be accounted for by the presence of monosulphide in the polysulphide solution, since a high yield of thioxane is obtained when  $\beta$ - $\beta'$  dichloroether is reacted with pure sodium monosulphide solutions. In this reaction only a small yield of the chain polymer,

is obtained as a somewhat granular white powder giving no evidence of elasticity whatsoever.

At this point it may be well to compare probable chemical structure of the unit of the polymers with gross physical properties in tabular form.

In view of the fact that whereas no rubber-like characteristics were exhibited by the ethylene disulphide polymer, but were developed when oxygen was present linked to the beta carbon atom as in the disulphide derivative of  $\beta$ - $\beta'$  dichloroether,

investigations are now in progress to determine whether or not the monosulphide derivatives can by any structural rearrangement be made to assume the typical rubber-like properties.

For example, by reacting sodium ethylene dimercaptide with dichloroether an interesting variation in the sequential arrangement can be made :

This polymer does not, however, exhibit rubber-like properties.

In consideration of the fact that one of the most remarkable properties displayed by several of the polysulphide polymers is their capacity to undergo a change at least superficially analogous to the vulcanisation of the diene polymers, a few comments on this phenomenon will be made.

As investigations are now in progress which it is hoped will clear up some of the more obscure points on the subject of cure or vulcanisation, no extended discussion would be justified.

The heat cure phenomena exhibited by the polysulphide polymers appear to involve in every case an oxidation process. Oxidising agents such as di- and tri-nitro benzene, benzoyl peroxide, etc., promote the cure, whereas reducing agents such as for example pyrogallol and zinc dust greatly retard and in many cases inhibit the curing process.

A number of metallic oxides are very effective in promoting cure, among which zinc oxide and cupric oxide are perhaps to be preferred. It should be noted also that a trace of moisture in the mix promotes the curing process.

For example, if the ether disulphide polymer is placed in a mould in a curing press, the platens of which are heated to  $145^{\circ}$  C. and the mould is exposed to this temperature for thirty minutes, then cooled and removed, no particular change is observed, except that the material is usually somewhat more plastic than before heating. If the time of exposure to the temperature is increased, a tendency to stickiness of the surfaces of the sample becomes noticeable. If, however, before subjecting to the curing temperature, 100 parts by weight of the plastic polymer are intimately mixed, or compounded, with 10 parts by weight of powdered zinc oxide and heated as described, a very different result is obtained. The rather plastic mass has taken the exact shape of the mould, and has developed toughness and "nerve." When a strip of the material is pulled out to an elongation of about 500 per cent. of its original length, the piece becomes warm and, when permitted to resume its former length, a perceptible cooling effect is noted. If stressed beyond its strength it breaks with a sharp snap.

If the time of exposure to temperature is doubled, the toughness of the material is found to have increased. The ultimate elongation at break has decreased, but the stress required to produce any given deformation (the modulus) has increased. When, in addition to the zinc oxide, about 20 parts by weight of carbon black is compounded with the polymer, all of the physical properties are markedly enhanced.

To show graphically the very marked change in physical properties, and presumably in internal structure, brought about by heating the polymer in the presence of suitable curing agents, a stress-strain diagram is presented. In this diagram, the loads required to cause a given elongation of the test specimen are plotted against the percentage of the original length represented by that elongation. For convenience points were chosen at 100 per cent. elongation and at multiples of 100 per cent. and a smooth curve drawn through the points so established. A low tensile soft stock was chosen, as such a compound shows most clearly the change in shape and the displacement of the curve with increasing time and/or temperature.

It is of interest to compare the general shape of these curves with the stress-strain diagram deduced on theoretical grounds for rubber by Mack.

The statement was made that the phenomena of cure displayed by the polysulphide polymers appear to be caused or accompanied by an oxidation process. Zinc oxide is not, however, ordinarily regarded as an oxidation agent.

Investigation has shown that when any of the vulcanisable polysulphide polymers is cured with zinc oxide, or zinc hydroxide since traces of moisture are invariably present and have in some cases been demonstrated to be essential, a certain amount of zinc sulphide is always present after cure. The exact proportion of zinc oxide changing to the sulphide during cure has not been determined with a sufficient degree of accuracy, on account of the very considerable experimental difficulties attending its quantitative separation from the vulcanised mass.

Obviously then, a certain amount of hydroxyl has been replaced by sulphur in combination with the zinc. When zinc hydroxide combines with sulphur a considerable potentiality for oxidation is displayed.

For example, when powdered zinc hydroxide is intimately mixed with powdered sulphur and the mixture is heated in a tube, a considerable amount of sulphur dioxide is evolved. The complete reaction may be represented as:

As it has been shown above in commenting on the hypothetical structure of the linear polysulphide polymers, the presence of terminal

FIG. 1.

—SH groups is a very plausible inference from their synthesis from the mercaptans. In a way the polymers may themselves be considered, according to this hypothesis, to be mercaptans of very high molecular weight.

Considered in this way, if it is shown that "vulcanisation" of these polymers always involves an oxidation, the thought immediately suggests itself that at the elevated temperatures used a further oxidation polymerisation takes place and that the "heat cure" of these polymers

involves only the raising of the average length of the chain to a higher level. In other words, two chains, one  $x$  units in length, and the other  $y$  units long, both having  $\text{—SH}$  end groups may undergo mutual oxidation if a terminal group of one happens to be in juxtaposition with a terminal group of the other to give,

the two original chains having coalesced through an  $\text{—S—S—}$  linkage to give a similar chain  $x + y$  units long.

This simple hypothesis would "explain" all the phenomena of heat vulcanisation as due to increase in the average molecular weight or increased degree of polymerisation. While it is probable that this hypothesis would account for a part and perhaps a large part of the phenomena of heat vulcanisation of the polysulphide polymers, it is also probable that other factors than linear polymerisation may play a part. For example, the marked increase in resistance to solvent penetration with increased cure would strongly suggest the possibility of cross linkages taking place with a "tying in" of the whole structure.

In the present state of the investigation, no mechanism by which this cross linking might take place can be suggested.

Aside from their scientific interest, several of the elastic polysulphide polymers have furnished the technologist with very valuable tools, because although they strongly resemble rubber in elasticity, capability of reinforcement and modification by pigments, and especially in their ability to undergo "cure" by heat in which they pass from a fairly plastic workable mass to a tough elastic final form; they differ uniquely from rubber and its cognate polymers in their chemical stability and their resistance to attack by organic solvents and by oxidation.

Certain of these polymers when properly compounded and cured are adaptable for use over a very wide temperature range. For example, compounds have been made which were as flexible at  $50^\circ\text{ F.}$  below zero as at ordinary temperatures, and the same compound underwent no appreciable change when immersed in hot lubricating oil for days at  $212^\circ\text{ F.}$

In view of the several hypotheses advanced in recent years to account for the extension-retraction elasticity of rubber, it would be of great interest to properly evaluate the significance of the peculiar analogies in physical behaviour of many of the polysulphide polymers when compared with the characteristic properties of rubber, because in spite of the obviously very different chemical constitution of the polysulphide polymers, it appears probable that the parallels are so numerous as to rule coincidence out of court, and that a more plausible assumption under the circumstances is that some fundamental structural similarity and spatial relationship obtains.

On the other hand, the very differences in chemical constitution of the rubber-like polysulphide polymers as compared with that of rubber and other diene polymers may be of service by shedding an oblique light on the subject of what is necessary in the way of chemical structure and space relationships to cause a molecule to be rubber-like.

## Summary.

A description has been given of certain highly rubber-like linear polymers derived from dihalogenated hydrocarbons and dihalogenated ethers when these compounds are reacted with polysulphides.

A theory of chemical structure has been suggested based on the oxidation-reduction phenomena exhibited by these polymers.

A partial theory of the mechanism of the heat vulcanization of these polysulphide polymers has been advanced.

## GENERAL DISCUSSION.

Dr. R. J. W. Le Fèvre (London) said: The reaction between methylene dichloride and alkali sulphide solutions having been expressed generally as  $\text{Cl} \cdot \text{CH}_2 \cdot \text{Cl} + \text{M}_2\text{S}_x = -\text{CH}_2\text{S}_x \cdot \text{CH}_2\text{S}_x \cdot \text{CH}_2\text{S}_x$ —it becomes of interest to remark that an entirely different course is followed when M is  $\text{NH}_4$  from that when it is Na or K. In collaboration with Mrs. C. G. Le Fèvre, an examination was made some years ago<sup>1, 2</sup> of the reaction between aqueous formaldehyde (by hydrolysis equivalent to  $\text{CH}_2\text{Cl}_2$ ) and solutions of ammonium sulphide or polysulphide. When these reagents were mixed, a white precipitate was formed after a definite period of induction which depended in a regular manner on the concentrations of the reactants and the temperature.<sup>3</sup> From analysis and various reactions of the substance, detailed in the references<sup>1, 2, 3</sup>, the conclusion was reached that it was a highly polymerised compound built up of units, shown in (I), associated together in much the same way as Hess<sup>4</sup> at one time supposed the glucose anhydride units to be in cellulose.

However, all the known facts are just as completely represented by the structure (II), which is now proposed. This has the advantage that it allows the gradual growth of macro-molecules to be formulated throughout by the accepted mechanisms (aldol additions and water eliminations) of current organic chemistry. The recorded physical properties, especially the solubility, suggests that  $n$  is a large number. This agrees with the analytical data<sup>1, 2</sup>, which corresponded with an empirical formula  $(\text{CH}_2)_n\text{N}_2\text{S}_2$  (I), inasmuch as a considerable number of the intermediate

<sup>1</sup> Le Fèvre and Le Fèvre, *J.C.S.*, 1932, 1142.

<sup>2</sup> *Ibid.*, 1932, 2087.

<sup>3</sup> Le Fèvre and Macleod, *J.C.S.*, 1931, 474.

<sup>4</sup> Hess, *et alia*, *Annalen*, 1923, 435, 1.

(CH<sub>3</sub>)<sub>3</sub>N<sub>2</sub>S<sub>2</sub> units have to be inserted between the head and tail groups of (II) before the percentage of sulphur is lowered and that of nitrogen is raised to the order of that found experimentally for each of these elements ; the variability of analyses with the manner of preparation (3) is also directly explicable on a basis of (II), since  $n$  should be expected to be affected by concentration of reactants, the temperature of reaction, etc.

## THE CONSTITUTION OF HYDROUS OXIDE GELS AND SOLS.

BY HARRY B. WEISER and W. O. MILLIGAN.

*Received 10th July, 1935.*

### Hydrous Oxide Gels.

Hydrous oxide is the general term applied to gelatinous precipitates thrown down from salt solutions when the  $p_H$  is above a certain value which varies with different salts. The term as we have used it for more than a score of years implies that gel water is retained by the colloidal particles as a result of adsorption and capillary forces ; hence the water content of a given hydrous oxide is purely accidental depending on the exact method of formation and drying, the temperature, and the age of the sample. A hydrous oxide differs from a hydrated oxide in that the water in the latter is chemically combined in definite stoichiometric proportions. Some hydrated oxides like  $Al_2O_3 \cdot H_2O$  and  $Fe_2O_3 \cdot H_2O$  give gelatinous precipitates which contain varying amounts of adsorbed water depending on the conditions of precipitation. Such preparations are designated as hydrous hydrated oxides. By the application of X-ray analytical methods, it has been established in a number of cases that hydroxyl groups are present. Gelatinous precipitates of such compounds are called hydrous hydroxides. On standing, the primary colloidal particles of the hydrous oxides and hydroxides grow and lose water spontaneously, causing the mass to assume a less gelatinous and more granular character. This spontaneous transformation from a loose voluminous precipitate to a granular mass is accompanied by a decrease in the solubility, the adsorbability, and the peptizability of the compounds.

The view that the hydrous oxide gels consist of colloidal particles of oxide or of a simple hydrate with adsorbed and entrained water was defended by van Bemelen<sup>1</sup> almost a half-century ago. This rather elementary concept of the constitution of the oxide gels is not accepted by certain investigators in this field. To illustrate the divergent views, a few typical oxide gels will be considered.

### The Brown Gel of Ferric Oxide.

**Dehydration Isobars.**—The dehydration isobars for the brown gel of ferric oxide, commonly prepared by adding a base to a solution of a ferric salt, are smooth curves showing no evidence of the presence of hydrates. Typical of such adsorption isobars are the curves of Simon and Schmidt<sup>2</sup> which are reproduced in Fig. 1. Curve I is for a relatively

<sup>1</sup> *Rec. trav. chim.*, 1888, 7, 106 ; *Die Absorption*, 1910.

<sup>2</sup> *Kolloid-Z. (Zsigmondy Festschrift)*, 1925, 36, 65.

coarse sample formed by precipitation from a ferric nitrate solution with ammonia, and Curve 2 is for a finer grained sample thrown down from a cold ferric chloride solution with ammonia.

Although the dehydration isobars for the brown gel indicate the absence of hydrates, there is a difference of opinion as to how the water is held. Hüttig<sup>3</sup> suggests that the water in hydrous oxides which give curves like those in Fig. 1, is "osmotically bound" water rather than water held in capillaries or adsorbed on the surface of the solid phase. This concept of osmotically bound water originated as a result of the observation that a number of the hydrous oxides give dehydration isobars like those in Fig. 1 which can be represented by an equation similar to van't Hoff's osmotic pressure law. Assuming that the osmotic pressure follows the gas laws, the van't Hoff equation takes the form

$$\ln \frac{p_0}{p} = \frac{n_1}{n},$$

in which  $p_0$  is the vapour pressure of pure water;  $p$ , the vapour pressure of the solution at the same temperature;  $n_1$ , the number of dissolved molecules; and  $n$ , the number of molecules of the solvent.

For oxide-water systems which give dehydration curves like those in Fig. 1, the value of  $n_1$  might be set equal to 1 since the amount of the dry solid phase is constant. It was found, however, that in order to make the equation fit, it was necessary to multiply the constant number of molecules of dry solid ( $n_1 = 1$ ) by an association or dissociation factor,  $k$ . The osmotic law equation thus takes the form

$$\log \frac{p_0}{p} = \frac{k}{n},$$

where  $p_0$  is the vapour pressure of pure water which is a function of the temperature;  $p$ , the constant vapour pressure at which the dehydration is carried out;  $n$ , the water content of the solid phase; and  $k$ , a constant. Applying this equation, the value of  $k$  has been found to be constant and equal to approximately 4 for the dehydration of hydrous zirconia and of hydrous thorina; 2, for hydrous titania; 3, for certain hydrous ferric oxides; 1, for hydrous lead peroxide; 3 or 7, for white hydrous tungstic oxide, etc. On the basis of these observations it was assumed that the water is osmotically bound by the solid phase. This means that oxide-water systems which obey the modified osmotic law are in reality solid

FIG. 1.—Dehydration isobars for hydrous ferric oxide.

<sup>3</sup> *Fortschr. Chem., Physik, physik. Chem.*, 1924, 18, 5; *Kolloid-Z.*, 1932, 58, 44.

solutions in which the water is free to move about in the solid phase. Hydrrous oxide gels like alumina, chromic oxide, certain samples of ferric oxide, etc., which give dehydration isobars that do not obey the modified osmotic equation, are assumed to be mixed types in which only a part of the water is osmotically bound, the remainder being held in capillaries or adsorbed on the surface of the solid. Similarly, a definite crystalline hydrate like yellow tungstic oxide monohydrate which gives a dehydration isobar without sharply defined steps, is assumed to be a mixed type in which a part of the hydrate water is chemically bound in the orthodox sense and a part is free to move throughout the crystal lattice of the solid phase.

Although Hüttig has shown that the dehydration isobar of certain hydrrous oxides may be represented approximately by a modified form of the osmotic equation, it does not follow that in such cases the water is in solid solution in the oxide. In the first place, one would expect to get the same general type of curve for the gradual loss of adsorbed water with rising temperature. Indeed, the dehydration isobars for hydrrous ferric oxide, hydrrous zirconia, etc., may be represented by an adsorption equation of the Freundlich type.<sup>4</sup> Moreover, many typical hydrrous oxides give curves which may be represented by the adsorption equation and which do not fit the modified osmotic equation. It does not follow necessarily in either case, that conformity of results with the equation is proof of the correctness of the assumptions on which the equation is based.

**Dehydration Isotherms.**—The dehydration isotherms of the brown gel are in general smooth curves which give no indication of hydrate formation; but Thiessen and Köppen<sup>5</sup> obtained isotherms with breaks indicating the formation of 8 to 10 different hydrates during the dehydration of a ferric oxide gel resulting from the hydrolysis of ferric ethylate. The experiments of Thiessen and Köppen have been repeated<sup>6</sup> and extended under very carefully controlled conditions which allowed ample time for equilibrium conditions to be set up. A typical set of isotherms which show no indication of breaks is reproduced in Fig. 2.

Foote and Saxton<sup>7</sup> attempted to determine the manner in which water was held, by observing the volume changes on freezing the precipitated oxide. They came to the conclusion that the water which freezes gradually with falling temperature is held in capillaries, whereas water which cannot be frozen is in the "combined" or "bound" state. The "combined" water is given up slowly on heating the precipitate with water, with no tendency toward simple ratios between ferric oxide and water; and when once dehydrated, the material does not take up water to form hydrates. It was assumed, therefore, that the ferric oxide and water "combine" in indefinite proportions, which is essentially a case of solid solution rather than of adsorption. It is now known that the failure of gel water to freeze at a certain temperature is no criterion for determining whether water is dissolved or adsorbed.<sup>8</sup>

Willstätter and co-workers<sup>9</sup> claim that the water in the gel is held in part as chemically combined hydrate water and in part as adsorbed

water in capillaries. They claim to be able to remove the latter by washing with acetone, leaving definite hydrates the composition of which depends on the conditions of drying. These claims are not justified even by Willstätter's experiments, and they are not taken seriously by many investigators (*cf.* section on stannic oxide gel).

**X-ray Observations.**—X-ray studies<sup>8</sup> on precipitated ferric oxide confirm and extend the results of dehydration experiments. A gel thrown down at room temperature was washed free from chloride with dilute ammonia and after washing with water, separate portions were allowed to stand at room temperature and at 100°. The ageing was followed by examining samples at intervals by X-ray diffraction methods. In Plate I, 3, are reproduced the densitometer curves of the X-ray negatives for the oxide aged at 100°. These show the gradual transformation of the gel into relatively large crystals of brick-red hematite,  $\alpha\text{-Fe}_2\text{O}_3$ . Similar changes take place at room temperature but the progress is slower.

FIG. 2.—Dehydration isotherms for hydrous ferric oxide from the hydrolysis of ferric ethylate

The above observations indicate that the transformation from brown gel to brick-red precipitate consists in the growth of particles too finely divided to give a characteristic X-radiogram into crystals of  $\alpha\text{-Fe}_2\text{O}_3$ , large enough to give sharp diffraction lines. This growth takes place slowly at room temperature but more rapidly at high temperatures. Gels thrown down at 100° give at once the  $\alpha\text{-Fe}_2\text{O}_3$  pattern and a gel precipitated at 50° and aged for a few hours at this temperature gives broad diffraction bands corresponding to  $\alpha\text{-Fe}_2\text{O}_3$ . It would appear therefore that the brown gel of ferric oxide contains no hydrate but consists of extremely minute particles of  $\alpha\text{-Fe}_2\text{O}_3$  with adsorbed water.

Krause and his collaborators<sup>10</sup> claim the existence of ortho- and meta-hydroxides of iron as well as a variety of products of ageing from a procedure which involves the synthesis of silver ferrites. Krause assigns definite molecular structures to the freshly formed gels and interprets the changes as a result of polymerisation, ring closure, aggregation, oxygen

<sup>10</sup> *Z. anorg. Chem.*, 1932, 204, 20, 385; 206, 328; 208, 282; 1933, 211, 98; 216, 577; 1934, 219, 203, 213.

bridging, etc. This view would appear to be of limited applicability even if one grants that the evidence demands such a formulation as Krause proposes for those gels which are too finely dispersed to give the  $\alpha$ - $\text{Fe}_2\text{O}_3$  diffraction pattern.

### The Alumina Gel.

The constitution of the gel thrown down from an aluminum salt with ammonia has been the subject of considerable controversy since Willstätter and Kraut<sup>11</sup> claimed to get a series of definite hydrates by precipitating aluminum sulphate with ammonia under varying conditions. A precipitate which Willstätter prepared by mixing 1 l. of 1 *N*  $\text{Al}_2(\text{SO}_4)_3$  at 100° and 1 l. of 6 *N*  $\text{NH}_4\text{OH}$  at 50°, followed by conducting in steam for five hours, was a pale yellow plastic mass *A*; without the steam treatment, it was a very pale yellow plastic mass *B*; with more dilute ammonia it was a pure white, very voluminous, and very finely divided substance, *C*. An intermediate variety *b*, prepared by the dialysis of aluminum chloride with frequent additions of small quantities of ammonia, was claimed to be related chemically to *B* but resembled *A* in adsorptive power; a modified form of *C* precipitated at 60° had an adsorptive capacity similar to *B*; and a new form of *A*<sup>12</sup> claimed to be  $\text{Al}_2\text{O}_3 \cdot 2\text{H}_2\text{O}$  was obtained by carrying out the precipitation at approximately 50°, washing by decantation four times, followed by the addition of 15 per cent. ammonia and further washing by decantation until peptisation started. As a result of dehydration experiments with the gels, Willstätter claimed to get various hydrates which gave certain temperature intervals of almost constant water content. Thus precipitates obtained at low hydroxyl ion concentration and washed with acetone which was tacitly assumed to remove adsorbed water, analysed approximately for trihydrate; and precipitates obtained with excess ammonia in the hot gave what were assumed to be poly-aluminum hydroxides such as  $2\text{Al}(\text{OH})_3 \cdot \text{H}_2\text{O}$ ,  $4\text{Al}(\text{OH})_3 \cdot 3\text{H}_2\text{O}$ , and so on up to  $8\text{Al}(\text{OH})_3 \cdot 7\text{H}_2\text{O}$ . X-ray analysis of the several preparations in the author's laboratory<sup>13</sup> showed that most of Willstätter's alleged hydrates have no existence in fact. Thus the preparations *A*, *B*, *C*, and new *A* all gave the X-ray pattern of the monohydrate,  $\gamma\text{-Al}_2\text{O}_3 \cdot \text{H}_2\text{O}$ .

Since the gels formed by Willstätter's procedures by precipitation at 50° or above are hydrous  $\gamma\text{-Al}_2\text{O}_3 \cdot \text{H}_2\text{O}$ , it seems probable that the gels thrown down at room temperature are likewise hydrous monohydrate. In support of this Rooksby<sup>14</sup> obtained diffuse  $\gamma\text{-Al}_2\text{O}_3 \cdot \text{H}_2\text{O}$  lines from a gel thrown down at room temperature and Havestadt and Fricke<sup>15</sup> found the same thing for a gel precipitated at 0° and washed eight hours by decantation.

On ageing at room temperature hydrous  $\gamma\text{-Al}_2\text{O}_3 \cdot \text{H}_2\text{O}$  goes over spontaneously into the metastable trihydrate  $\alpha\text{-Al}_2\text{O}_3 \cdot 3\text{H}_2\text{O}$  or bayerite and thence to the stable  $\gamma\text{-Al}_2\text{O}_3 \cdot 3\text{H}_2\text{O}$  or gibbsite. Since the X-ray diffraction patterns of trihydrates obtained by different people are not always the same but are similar in certain respects to the gibbsite pattern, we believed at one time that the samples were mixture of  $\gamma\text{-Al}_2\text{O}_3 \cdot 3\text{H}_2\text{O}$

<sup>11</sup> *Ber.*, 1923, **56B**, 149, 1117; 1924, **57B**, 1082; 1925, **58B**, 2451.

<sup>14</sup> *Trans. Ceram. Soc. England*, 1929, **28**, 399.

<sup>15</sup> *Z. anorg. Chem.*, 1930, **188**, 357.

and  $\alpha\text{-Al}_2\text{O}_3 \cdot \text{H}_2\text{O}$  in varying proportions. It is now known,<sup>16</sup> however, that samples of the metastable isomer  $\alpha\text{-Al}_2\text{O}_3 \cdot 3\text{H}_2\text{O}$  are likely to contain more or less of the stable isomer, and that this apparently accounts for the differences in the bayerite patterns obtained by different investigators and the presence in them of lines corresponding to  $\gamma\text{-Al}_2\text{O}_3 \cdot 3\text{H}_2\text{O}$ . In a study of the transformation from monohydrate to trihydrate by isobaric dehydration and X-ray diffraction methods, Hüttig<sup>17</sup> was led to conclude that a continuous series of crystalline hydrates between the two extreme compositions are formed. It is much more probable that the intermediate products were not definite chemical individuals as Hüttig suggests but were mixtures of  $\gamma\text{-Al}_2\text{O}_3 \cdot \text{H}_2\text{O}$ ,  $\alpha\text{-Al}_2\text{O}_3 \cdot 3\text{H}_2\text{O}$  and  $\gamma\text{-Al}_2\text{O}_3 \cdot 3\text{H}_2\text{O}$  in varying amounts depending on the conditions of precipitation and the age and treatment of the sample.

Although the existence of  $\gamma\text{-Al}_2\text{O}_3 \cdot \text{H}_2\text{O}$  has been definitely established it does not give a "step" dehydration isobar. Moreover, in the dehydration of gibbsite,  $\gamma\text{-Al}_2\text{O}_3 \cdot \text{H}_2\text{O}$  is formed as an intermediate product but one would never know it from the form of the dehydration isobar which gives no break corresponding to the monohydrate. Finally the X-ray diffraction pattern for  $\gamma$ -monohydrate persists below a composition corresponding to  $\text{Al}_2\text{O}_3 \cdot 0.35\text{H}_2\text{O}$ . The cause of this anomalous behaviour in the dehydration of alumina gel and of alumina trihydrates calls for special consideration.<sup>16</sup>

FIG. 4.—Dehydration isobars for  $\gamma\text{-Al}_2\text{O}_3 \cdot 3\text{H}_2\text{O}$ .

Application of the phase rule to the two-component system hydrate-oxide-water vapour, shows that the system should be univariant. The type of isobar is given by the lines  $AB$  and  $BC$  in Fig. 4. Theoretically, the curve should drop to zero composition at a definite temperature, but actually the isobars are usually rounded off as shown in the figure by the line  $ADC$ . This is due to loss of part of the water below the true decomposition temperature of the mass of the hydrate on account of lattice distortion, strain in the crystals, and variation in crystal size. Now if the oxide formed by the dehydration of the hydrate is highly hygroscopic, it will adsorb most of the water vapour. Hence the actual dehydration measured is the loss of adsorbed water from the oxide. In such cases a bivariant type of curve is to be expected, as shown by the

<sup>16</sup> Weiser and Milligan, *J. Physic. Chem.*, 1934, **38**, 1175.

<sup>17</sup> Hüttig and Wittgenstein, *Z. anorg. Chem.*, 1928, **171**, 329; Hüttig and Kostelitz, *ibid.*, 1930, **187**, 11.

solid line *AE* in Fig. 4. It is precisely this last type of curve which Fricke and Severin<sup>18</sup> obtained for both  $\alpha$ - and  $\gamma$ - $\text{Al}_2\text{O}_3 \cdot \text{H}_2\text{O}$ .

The loss of water by a hydrate below a definite decomposition temperature is attributed by Damerell<sup>19</sup> to surface dehydration of extremely minute crystals, without lattice rearrangement. This view is unsatisfactory since one gets a similar form of curve even with macroscopic crystals. As already pointed out, Hüttig explains the absence of sharply defined steps in the dehydration isobars of hydrates by postulating that a part of the definite hydrate water is "osmotically bound." This view appears less tenable in the case of definite hydrates than in the case of gels of the anhydrous oxides.

We can now explain the persistence of the X-radiogram of the monohydrate where it would ordinarily not be expected to exist. The X-radiogram for the monohydrate should persist along the broken curve *ADC* because some monohydrate exists as such and the extremely hygroscopic  $\gamma$ - $\text{Al}_2\text{O}_3$  formed by partial decomposition of the former is either amorphous or too finely crystalline to be detected by X-ray analysis.

In a higher hydrate decomposing first into a lower hydrate and finally into the anhydrous substance, it is apparent that, under the conditions noted above, the isobar will fail completely to detect the lower hydrate. In Fig. 4 the theoretical curves for the case of a trihydrate decomposing to a monohydrate and this in turn to the oxide are given by the broken lines *FGHBC*. The actual experimental curve as obtained by Weiser and Milligan<sup>16</sup> is given by the solid line. The composition of the trihydrate remains constant until at point *F* some water is lost, giving a small amount of water vapour and monohydrate. As this process continues along *FKH*, all the trihydrate decomposes rapidly, giving monohydrate. Now at this temperature the lower hydrate loses water to point *O*, and hence the line *FKH* continues past the theoretical composition of the monohydrate to the point *O*. This decomposition of the monohydrate gives the highly adsorptive  $\gamma$ -oxide, the presence of which causes the dehydration to proceed along the line *HOE* for the reason given above.

### Stannic Oxide Gel.

By drying different precipitated stannic oxides under suitable conditions, a number of supposedly definite oxide hydrates were formed. The vapour pressure isotherms of van Bemmelen<sup>1</sup> failed to establish the existence of any definite hydrate in the gel and suggested that compositions corresponding to a hydrate were purely accidental. Van Bemmelen's observations were confirmed and extended and his conclusions reaffirmed by Lorentz,<sup>20</sup> Mecklenburg,<sup>21</sup> and Weiser.<sup>22</sup> In recent years, however, Willstätter and his collaborators<sup>23</sup> adopted the older view that the behaviour of the variety of oxides could be explained best by assuming the existence of more or less stable hydrates. Willstätter claimed to remove all the adsorbed water from a compound by

<sup>18</sup> *Z. anorg. Chem.*, 1932, 205, 287.

<sup>19</sup> Damerell, *J. Physic. Chem.*, 1931, 35, 1061; Damerell, Hovorka, and White, *ibid.*, 1932, 36, 1255.

<sup>20</sup> *Z. anorg. Chem.*, 1895, 9, 369.

<sup>21</sup> *Ibid.*, 1909, 64, 368; 1912, 74, 207; 1913, 84, 121.

<sup>23</sup> *Ber.*, 1924, 57B, 63, 1491; 1926, 59B, 2541; *Kolloid-Z.*, 1929, 49, 353.

drying rapidly in vacuum or by leaching with acetone. The composition of a gel formed in a special way, and dried by the acetone method at  $-35^{\circ}$  to  $+10^{\circ}$ , was represented by the formula  $\text{Sn}(\text{OH})_4 \cdot \text{H}_2\text{O}$ ; but when dried at room temperature the analysis showed a composition  $\text{Sn}(\text{OH})_4$ , which was regarded as the first member of a series of  $\alpha$ -stannic acids. In an aqueous medium,  $\text{Sn}(\text{OH})_4$  was supposed to go over into other less basic members of the series. Thus by suitable conditions of precipitation and drying with acetone at  $0^{\circ}$  to  $10^{\circ}$ , orthodistannic acid was supposedly formed; at  $35^{\circ}$  to  $46^{\circ}$ , orthotristannic acid; and so on. Different so-called  $\beta$ -stannic acids were likewise prepared and many of them assigned formulas.

As proof of hydrate formation, Willstätter cites the regions of almost constant water content in the temperature-composition curves of acetone-dried preparations. Such evidence is altogether inconclusive, particularly when the nature and location of the "flats" in the curves are determined almost exclusively by the history of the sample. The same may be said of the "flats" in the vapour pressure curves of van Bemmelen. The adsorptive capacity of a hydrous oxide for water at different stages of dehydration is determined by the physical character of the preparation; hence a "flat" corresponding to a definite hydrate is purely accidental and can be duplicated only by following a set method of procedure in precipitation, ageing, and drying. Willstätter's comparison of the behaviour of hypothetical, high-molecular, hydrated, stannic acids with their groups  $\text{Sn} : \text{O}$  and  $\text{Sn} : \text{OH}$ , to that of carbohydrates with the groups  $\text{C} : \text{O}$  and  $\text{C} : \text{OH}$ , appears highly fantastic and illusionary. As Posnjak<sup>24</sup> points out: "Willstätter and his collaborators did not bring forth a single new fact, but rather take the problem back some fifty years and only add to the confusion."

Fortunately, Posnjak was able to settle the question of the composition of the so-called  $\alpha$ - and  $\beta$ -stannic acids by the aid of X-ray diffraction analysis. Samples of the so-called  $\alpha$ - and  $\beta$ -oxides were found to give identical diffraction patterns which in turn were identical with that of the mineral cassiterite—anhydrous stannic oxide. This result has been confirmed by Förster<sup>25</sup> and by Hüttig and Döbling,<sup>26</sup> so that the facts are quite well established. The  $\alpha$ - and  $\beta$ -stannic oxides are not isomers but are structurally the same: stannic oxide with more or less adsorbed water. The differences in properties are due to the size and extent of coalescence of the primary particles into secondary aggregates. Similar conclusions were reached by Pascal<sup>27</sup> from measurements of the molecular susceptibilities of various preparations.

In spite of the conclusive nature of the evidence against the existence of isomeric forms and hydrates of stannic oxide, Thiessen and Koerner<sup>28</sup> claim that a stannic oxide gel prepared by the slow hydrolysis of an alcoholic solution of stannic ethylate gives pressure-temperature and composition-temperature curves that indicate the formation of no less than six definite hydrates. This could not be confirmed in the author's laboratory<sup>29</sup> as shown by the dehydration isobar given in Fig. 5, together with similar isobars for typical  $\alpha$ - and  $\beta$ -oxides. In every case, smooth

<sup>24</sup> *J. Physic. Chem.*, 1926, **30**, 1073; Yamada, *J. Chem. Soc. Japan*, 1923, 44, 210.

<sup>29</sup> Weiser and Milligan, *J. Physic. Chem.*, 1932, **36**, 3030.

curves were obtained indicating the absence of hydrates. The change in direction at a temperature of  $60^{\circ}$ - $70^{\circ}$  with the oxide made by Thiessen and Koerner's method is not due to a hydrate but to the presence of adsorbed alcohol in the sample. The breaks in the curves of Thiessen and Koerner appear to be the result of faulty technique, possibly the failure to allow sufficient time for equilibrium to be established under

FIG. 5.—Dehydration isobars for hydrous stannic oxides.

a given set of conditions. Finally, X-ray diffraction patterns of samples obtained by dehydrating Thiessen and Koerner's gel at definite temperatures, show that no definite hydrates are actually formed: the several alleged hydrates were found to consist of stannic oxide (cassiterite) of varying particle size

with varying amounts of adsorbed water.

From the above and other similar observations it is concluded that, for the most part, gelatinous precipitates of the oxides are not polymerised bodies or condensation products resulting from the splitting off of water from hypothetical metallic hydroxides. Instead, they are believed to consist of an agglomerate of extremely minute crystals of oxide or of a simple hydrate (or hydroxide) which holds large amounts of water by adsorption and capillary forces.

### Hydrous Oxide Sols.

Hydrophobic sols such as those of the hydrous oxides can be prepared fairly free from electrolytes but it was demonstrated first by Thomas Graham and confirmed repeatedly thereafter, that in the absence of protecting colloids, some electrolyte must be present in the sols to ensure their stability. Thus ferric oxide sol formed by hydrolysis of ferric chloride or by peptisation of the hydrous oxide by ferric chloride always contains traces of chloride however long the dialysis is continued.

The presence of chloride in the dialysed sols led Wyruboff and Verneuil<sup>30</sup> to suggest that the various preparations contain basic salts or chlorides of "condensed" hydroxides. This idea was further extended and developed by several investigators especially by Duclaux, Malfitano, Hantzsch and Desch, and Linder and Picton. The view that the oxide sols are oxy salts or basic salts meets with serious objection at the outset since definite chemical oxychlorides or basic chlorides are seldom encountered. No oxychloride of aluminium has been established with

<sup>30</sup> *Bull. soc. chim.*, 1899, (3), 21, 137.

certainty and but one ferric oxychloride has been identified, the compound  $\text{FeOCl}$  prepared by Stirnemann<sup>31</sup> by heating a solution of ferric chloride in a bomb tube between  $270^\circ$  and  $410^\circ$ . The idea that Graham's ferric oxide sol contains a basic salt gained support from Böhm's<sup>32</sup> observation that the particles in an aged sol gave an X-radiogram for a basic salt identical with that said to be obtained by the slow hydrolysis of ferric chloride. It has been established<sup>33</sup> however, that the alleged basic salt is in reality  $\beta\text{-Fe}_2\text{O}_3 \cdot \text{H}_2\text{O}$  with varying amounts of adsorbed chloride depending on the conditions of formation and the treatment.

Pauli<sup>34</sup> considers the colloidal particles to be complex colloidal ions resulting from ionisation of complex electrolytes allied to the Werner compounds. Since the constitution of a given sol varies with the conditions of preparation, he represents it by a general formula. In the case of ferric oxide sol this is  $(x\text{Fe}(\text{OH})_3 \cdot y\text{FeOCl} \cdot \text{FeO})^+$ ,  $\text{Cl}^-$  in which  $x = 32$  to  $350$  and  $y = 2.16$  to  $18$  in sols formed by peptisation and  $x = 33$  to  $150$  and  $y = 4$  to  $5.7$  in sols formed by hydrolysis. It is difficult to justify this formulation since no one has established the existence of  $\text{Fe}(\text{OH})_3$ , and  $\text{FeOCl}$  is obtained only under special conditions in a bomb tube at elevated temperatures.

Thomas and co-workers<sup>35</sup> suggest that the dispersed phase in hydrous oxide sols such as alumina sol formed by peptisation of the gel with hydrochloric acid, consists of olated and possibly oxolated aluminum oxychloride complexes of the Werner type resembling the poly-ol basic salts formulated by Bjerrum. This assumption was made to account for the observation that the  $p_{\text{H}}$  value of the sol is raised by the stepwise addition of neutral electrolytes, the anion order being: oxalate  $>$  acetate  $>$  sulphate  $>$  halides  $>$  nitrate. The increased  $p_{\text{H}}$  value was attributed to replacement of OH groups by the anion of the added salt, followed by the union of the displaced OH radicals with hydrogen to form water.

Since hydrous oxide sols formed in the presence of chloride, say, always contain more or less chloride, Thomas believes that such sols should be designated as metallic oxychloride sols rather than as hydrous oxide sols. He recognises that the term ferric oxychloride hydrosol is objectionable since it connotes a definite chemical compound when no such meaning is intended. Nevertheless he prefers to regard the hydrous oxide sols as oxysalt sols since the colloidal particles are not pure hydrous oxides. To be consistent, one should rename the metallic sols and the salts sols which like the oxide sols are not pure insoluble metal or salt. It is difficult to see what would be gained by introducing such a change in our terminology. The ratio of iron to chlorine in a ferric oxide sol has been variously reported as 6, 42, 84, 396, 2700 and higher. To designate a sol with a low chloride content as an oxychloride sol is like calling precipitated barium sulphate a chlorosulphate because it contains some adsorbed barium chloride.

It is now quite generally recognised that the stability of a positive silver halide sol is due to the preferential adsorption of silver ion by unsaturated secondary valence forces on the surface of the crystals. The

<sup>31</sup> *Neues. Jahrb. Mineral., Geol.*, 1925, **52A**, 356.

<sup>32</sup> *Z. anorg. Chem.*, 1925, **149**, 219.

<sup>33</sup> Weiser and Milligan, *J. Am. Chem. Soc.*, 1935, **57**, 438.

<sup>34</sup> Pauli-Valko, *Elektrochemie der Kolloide*, 1929.

<sup>35</sup> *J. Physic. Chem.*, 1931, **35**, 27; *J. Am. Chem. Soc.*, 1932, **54**, 841; 1934, **56**, 794, 1844.

crystals will also contain some adsorbed silver nitrate. Similarly a hydrous oxide sol formed in the presence of metallic chloride, hydrochloric acid, and their corresponding ions, will contain varying amounts of the several components depending on the precise method of formation and the purification of the sol. The positive charge on a given sol is due to the preferential adsorption of hydrogen and metallic ion on the surface of the hydrous oxide just as the positive charge on a silver halide sol is due to preferential adsorption of silver ion. It is unnecessary to attribute the charge to the presence of an "ionogenic complex attached to the surface" (Pauli) unless the presence of such a complex has been rendered highly probable. Thus to assume the presence of even a simple salt like  $\text{FeOCl}$  in a ferric oxide sol goes well beyond the established facts.

Some light has been thrown on the constitution of hydrous oxide sols, indirectly from observations of the phenomena which occur during the coagulation by electrolytes and directly from X-ray diffraction studies. These will be illustrated by a few specific examples.

### Titration of Sols with Salts.

Linder and Picton<sup>36</sup> showed that chloride ion passes into solution by exchange with sulphate when a ferric oxide sol prepared from ferric chloride is coagulated by potassium sulphate. This observation has been confirmed and extended by Pauli<sup>37</sup> who regards the precipitation process as a chemical reaction with the formation of an insoluble salt which he formulates as follows:  $2[(x\text{Fe}(\text{OH})_3 \cdot y\text{FeOCl} \cdot \text{FeO})\text{Cl}] + \text{K}_2\text{SO}_4 = [x\text{Fe}(\text{OH})_3 \cdot y\text{FeOCl} \cdot \text{FeO}]_2\text{SO}_4 + 2\text{KCl}$ . Such a formulation fails to take into account the fact that the alleged insoluble chlor-sulphate does not precipitate like simple insoluble compounds do, but comes down all at once after a critical concentration of sulphate is added. This and other phenomena observed when precipitating electrolyte is added stepwise to the sol indicate the inadequacy of the solubility theory.

In the coagulation of positively charged sols formed from metallic chloride, the precipitating anion is taken up by the particles in exchange with chloride. Rabinovich and Kargin<sup>38</sup> followed the change in the chloride ion concentration potentiometrically on adding sulphate and other anions stepwise to a definite amount of sol. Since they failed to allow time for equilibrium conditions to be established, erroneous conclusions were drawn from their observations.<sup>39</sup> To overcome this objection the following procedure has been employed in the author's laboratory:<sup>40</sup> Pure freshly precipitated calomel was suspended in the aged hydrous oxide sol. A 20-c.c. portion of the sol was placed in the outer compartment of a glass mixing apparatus and a definite amount of electrolyte diluted to 5 c.c. in the inner compartment. After mixing, the mixture was transferred to a small bottle which was kept in the thermostat at 25° for 2 days, shaking at intervals to saturate with calomel. The mixture was then placed in an electrode vessel consisting of a 30 c.c. weighing bottle in the bottom of which was sealed a platinum

wire making contact with mercury in the bottom of the vessel. After 24 hours the potential of the resulting half-element was measured against

FIG. 6.—Titration curves for ferric oxide sol with electrolytes.

a standard calomel electrode. A series of such half-elements was made with the amount of electrolyte increasing stepwise. Some observations on the titration of a ferric oxide sol containing 435 millimols  $\text{Fe}_2\text{O}_3$  and

16.6 millimols Cl per litre are shown in Fig. 6. Similar observations were made on alumina sols and, at the same time, the change in the  $\text{pH}$  value following the stepwise addition of electrolyte was determined. Typical results are illustrated in Figs. 7 and 8. In Fig. 7 are given the titration curves with  $\text{K}_2\text{C}_2\text{O}_4$  for an alumina sol formed by pep-

FIG. 7.—Titration curves for "grown" alumina sol.

tising "grown" alumina with dilute HCl. In Fig. 8 are given typical curves showing the simultaneous displacement of chloride and adsorption

of sulphate by a Graham alumina sol. The precipitation value is indicated by the short vertical line.

Observations of the above and other phenomena which take place during the coagulation process may be summarised as follows: (1) At the precipitation value of potassium salts of multivalent ions, the chloride in the supernatant solution is equivalent to or but little greater than the amount of added electrolyte. (2) Only a part of the chloride that is found in the supernatant solution after precipitation, can be detected potentiometrically in the original sol before adding electrolyte. Not all the chloride in the micelles is displaced by an excess of precipitating electrolyte. (3) The chloride measured potentiometrically, following

FIG. 8.—Curves showing simultaneous displacement of chloride and adsorption of sulphate on titrating alumina sol with  $K_2SO_4$ .

the stepwise addition of electrolyte, consists of the chloride in the sol originally, together with an additional amount that is displaced when the added anion is taken up. (4) The multivalent ions investigated are taken up practically completely by the sol particles in concentrations up to and including the precipitation concentration. The chloride displaced so that it can be detected potentiometrically is less than half the amount equivalent to the multivalent ion taken up.

(5) The amount of chloride displaced follows nearly a linear course at the outset of the stepwise addition of multivalent ions but becomes proportionately greater as the precipitation concentration is approached. (6) The chloride displacement curves for multivalent ions of varying valence follow a similar course until the precipitation concentration is approached, when a marked divergence for ions of different valence is observed. (7) The three salts of divalent anions exhibit a strikingly similar behaviour as regards the entire course of the chloride displacement curves and the precipitating power. (8) The trivalent ferricyanide coagulates at a distinctly lower concentration than the divalent ions, and the chloride displaced at the precipitation value is proportionately less with the former than with the latter. (9) The chloride displacement curve with

potassium salts of univalent ions, such as nitrate, follows a course distinctly lower than that for the multivalent ions. (10) The  $p_H$  value of the sols is increased by the stepwise addition of salts, the effect being more marked with salts possessing a buffer action such as acetate, citrate, and oxalate.

To account for the above results it is assumed that the constitution of the positive sol may be represented diagrammatically as shown in Fig. 9a taking alumina sol as an example. This indicates that the particles are essentially hydrous alumina monohydrate but since they contain some chloride that is difficult to displace the composition which varies with the condition of formation is represented by some point in the three component diagram  $Al_2O_3 \cdot HCl \cdot H_2O$  which may be represented symbolically as  $xAl_2O_3 \cdot H_2O \cdot yHCl \cdot zH_2O$ . Since the oxide shows such a strong tendency to adsorb aluminum and hydrogen ions as com-

FIG. 9.—Diagrammatic representation of the constitution of alumina sol: (a) before and (b) after the addition of sulphate.

pared with chloride, the particles are surrounded by an ionic double layer with the cations in the inside and chloride on the outside. The inner portion consists of adsorbed aluminum and hydrogen ions in adsorption equilibrium with the corresponding cations in the intermicellar liquid. The outer portion consists of a diffuse layer<sup>41</sup> of chloride ions most of which are held by the electrostatic attraction of the adsorbed positive inner layer but a part of which, because of relatively higher kinetic energy exert sufficient osmotic repulsive force against the attraction of the inner layer to influence the calomel electrode and so may be detected potentiometrically. The latter are represented in the diagram beyond the dotted circle.

This diagrammatic representation of the structure of the micelles indicates (1) its variability in composition as regards its water and chloride content, (2) the source of its positive charge, and (3) the reason only a part of the chloride can be detected potentiometrically.

<sup>41</sup> Gouy, *J. Physique*, 1910, (4), 9, 457.

On adding a coagulating electrolyte such as potassium sulphate to the sol, the divalent sulphate being more strongly adsorbed than chloride forces itself into the double layer closer to the adsorbed hydrogen and aluminum ions as indicated diagrammatically in Fig. 9b. Potentiometric analysis enables one to determine the chloride displaced. The difference between the chloride in the sol originally and that after the addition of sulphate, in other words, the displaced chloride, is not equivalent to the adsorbed sulphate since a part of the sulphate which enters the layer corresponds to chloride measurable potentiometrically in the original sol.

The adsorbed sulphate lowers the potential on the particle in the following way: A sulphate ion has the same average kinetic energy as a chloride ion but it possesses double the charge. Accordingly, if one assumes for the moment that the valence only determines the adsorbability, the divalent particles in the outer layer would be drawn closer to the inner layer and the thickness of the double layer would be decreased. Since the potential difference between two layers of opposite sign with constant charge density is directly proportional to the distance between them, it follows that the reduced thickness of the layer will be accompanied by a decrease in potential on the particle.

Since with ferric oxide sol the three divalent ions: sulphate, oxalate, and chromate, exhibit such a strikingly similar behaviour in displacing chloride and in reducing the potential to the coagulation value, it follows that with these three ions the valence is the most important factor determining the adsorbability.

The behaviour of trivalent ions such as ferricyanide would follow from what has been said. The ions having the same average kinetic energy but with three charges will be drawn closer to the inner layer than the divalent ions, and the further reduction in thickness of the double layer manifests itself in a lower precipitation value. The chloride ion displaced is obviously less, since less ferricyanide than divalent ion needs to be adsorbed to lower the charge on the particles to the coagulation value.

The adsorption of both the divalent and trivalent ions is sufficiently great that the amount necessary to cause coagulation is practically completely adsorbed.

The lowering of the potential on the particles results in coalescence and agglomeration of the particles with a consequent decrease in specific surface. This manifests itself in an increase in the amount of chloride displaced for a given increment in the multivalent ion added as the region of rapid coagulation is approached. Hence the upward bend in the chloride-displacement curve with multivalent ions, becomes more marked in the region of rapid coagulation. Above the coagulation point, the chloride is displaced from the precipitate by exchange adsorption without any marked decrease in specific surface, and the curve follows the usual course of the adsorption isotherm. This combination of conditions accounts for the S-shape of the chloride-displacement curve with all electrolytes having a high precipitating power and causing rapid coagulation above a critical concentration.

The increase in the  $p_H$ -value of hydrous oxide sols on adding a neutral salt especially those with multivalent anions, is doubtless due chiefly to the increased adsorption of hydrogen ion in the presence of a strongly adsorbed anion. This increased adsorption of cations in the presence of strongly adsorbed anions is a general phenomenon that has been observed

with various types of adsorbents such as carbon and fibres as well as with the hydrous oxides. With salts such as citrates, oxalates and acetates, buffer action increases the  $p_H$  value of the sol-electrolyte mixture above that of the sol alone. Iyer<sup>42</sup> accepts our formulation of the constitution of certain oxide sols but suggests that the outer layer may contain hydroxyl ions as well as chloride ions. The displacement of the former on titrating with neutral salts would account for the increase in  $p_H$  value of the mixture.

### X-ray Diffraction Studies.

Since X-ray diffraction studies have proven helpful in determining the composition of gels it was believed that similar studies on sols might give direct evidence of the constitution of the colloidal particles in the sols. The chief complication in the examination of such systems is the relatively low concentrations of the solid phase and the scattering of the X-rays by the water in the samples. Böhm and Niclassen<sup>43</sup> showed that the gels from certain oxide sols were not amorphous but in most cases it was not stated whether the air-dried or moist gel was examined. Since Thomas believes that the elements of water in certain oxide sols are combined in the form of poly-ol basic Werner salts, it is not permissible to air-dry the samples before examination. On the contrary, the sols must be studied directly, or the undried gel obtained preferably by ultrafiltration of the sols must be examined. The first experiments were carried out with the gels obtained by ultrafiltration of the following typical sols: (1) Hydrous alumina sols formed by peptisation with hydrochloric acid of (a) the gel thrown down at 100° from aluminum chloride solution with ammonia, and (b) the gel formed by the action of hot water on amalgamated aluminum. Thomas' procedure in making the sol from amalgamated aluminum was employed. (2) Hydrous stannic oxide sols prepared by the method of Zsigmondy. (3) Hydrous indium oxide trihydrate sol obtained by peptising the precipitated gel with hydrochloric acid.

The X-ray diffraction patterns of the moist gels were obtained in a Seemann-Bohlin type camera. Copper radiation filtered through nickel foil, at 60 milliamperes and 50,000 volts was employed. Under these conditions but 5-10 minutes exposure was necessary, so that little or no drying of the gel took place. The results of some observations are shown in diagram form in Fig. 10. From these observations it would appear that the particles in the alumina sols consist essentially of hydrous  $\gamma\text{-Al}_2\text{O}_3 \cdot \text{H}_2\text{O}$ . There is no reason to believe that they are made up of simple basic salts or basic salts of the Werner type. The gel from the stannic oxide sol gives the pattern of anhydrous  $\text{SnO}_2$  (cassiterite) and that from the indium oxide sol the pattern of  $\text{In}_2\text{O}_3 \cdot 3\text{H}_2\text{O}$ . A thixotropic stannic oxide sol gave a good cassiterite pattern.

From the above X-ray studies, it would appear that the particles in typical oxide sols consist essentially of aggregates of minute crystals of hydrous oxides or of simple oxide hydrates. In the sols containing chloride, the latter is not bound in the form of a basic salt in most cases, but is adsorbed in amount depending on the size and physical character of the particles. Such sol systems whose constitution may be represented diagrammatically as shown in Fig. 9, are properly referred to as hydrous oxide sols.

<sup>42</sup> *Proc. Indian Acad. Sci.*, 1934, 1, 372.

<sup>43</sup> *Z. anorg. Chem.*, 1924, 132, 1.

In the light of the above, if one prefers to regard the hydrous oxide sols as electrolytes with colloidal ions it must be emphasised that there is a fundamental difference between sols and non-colloidal complex electrolytes such as potassium ferrocyanide, the cobaltammines, the complex platonic salts, etc., formulated by Werner. There is also a

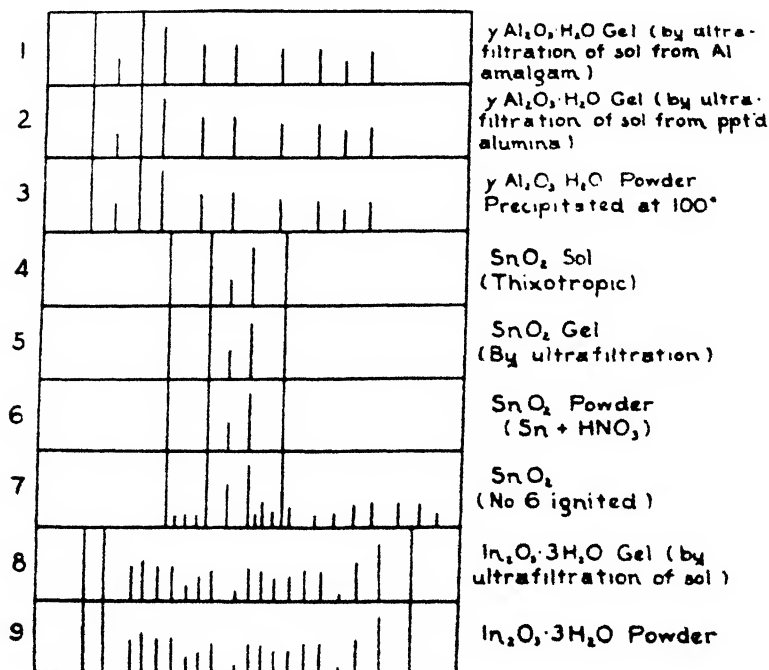

FIG. 10.—X-ray diffraction patterns for hydrous oxide gels and sols.

distinct difference between a hydrous oxide sol and such colloidal electrolytes as the soaps and Congo red in that the latter contain ionic micelles made up of groups of ions which have a definite composition and which carry one charge for each equivalent of the ion, whereas the micelles of the former have no definite composition and may carry hundreds or thousands of equivalents for each free charge.

### Summary.

The results of this communication may be summarised as follows:—

1. The constitution of hydrous oxide gels is deduced from experimental evidence obtained by phase rule and X-ray diffraction studies on the typical metallic oxides of iron, aluminum, and tin. The constitution of the hydrous oxide sols is formulated from the results of potentiometric studies on the titration of ferric oxide and alumina sols with electrolytes, and from X-ray diffraction studies on the hydrous oxide sols of aluminum, tin, and indium.

2. It is concluded that, in general, gelatinous precipitates of the oxides are not polymerised bodies or condensation products resulting from the splitting off of water from hypothetical unmetallic hydroxides. Instead they are believed to consist of agglomerates of extremely minute crystals of oxide or simple hydrate (or hydroxide) which hold large amounts of water by adsorption and capillary forces.

3. It is believed that the particles in typical oxide sols consist essentially of aggregates of minute crystals of hydrous oxide or of simple oxide hydrate. In sols containing chloride the latter is not bound in the form of basic salts or Werner complexes in most cases, but is adsorbed in amount depending on the size and physical character of the particles. To account for the properties of positive sols of which ferric oxide sol is typical, the constitution of the particles may be formulated as follows:

The Rice Institute,  
Houston, Texas.*

### GENERAL DISCUSSION.

**Professor E. C. C. Baly and W. P. Pepper (Liverpool) (communicated):**  
**The Hydrous Oxide Gels of Nickel and Cobalt.**—In view of the important communication by Professor Weiser and Dr. Milligan some quantitative observations with the hydrous gels of nickel and cobalt may be of interest.

It was stated by Proust in 1805 that anhydrous  $\text{Ni}_2\text{O}_3$  may be prepared by gently heating precipitated nickel carbonate in an open dish. This reaction has been investigated with nickel carbonate and hydroxide, and it has been found that, though the product is black, the  $\text{Ni}_2\text{O}_3$  content is only from 2.4 to 4.7 per cent., the amount depending to some extent on the method of preparation. Exactly the same result is obtained when nickel carbonate is completely decomposed to  $\text{NiO}$  by heating at  $250^\circ$  in a high vacuum and the cooled oxide is brought into the air. If cobalt carbonate is treated in either of the above ways a quantitative yield of  $\text{Co}_2\text{O}_3$  is obtained. It is interesting to note that when  $\text{CoO}$ , prepared by heating the carbonate in a high vacuum and allowed to cool to room temperature, is brought into the air it becomes red hot.

These facts, coupled with the fact that  $\text{Ni}_2\text{O}_3$  is endothermic with respect to  $\text{NiO}$ , clearly indicate that the formation of  $\text{Ni}_2\text{O}_3$  by the above methods must be due to the surface oxidation of crystal units of  $\text{NiO}$ . Since  $\text{NiO}$  is cubic, it is possible to calculate the size of these crystal units from the amount of  $\text{Ni}_2\text{O}_3$  formed. If  $x$  be the number of Ni and O atoms in the edge of the cube, the number of atoms in the surface of the cube will be  $x^2 - (x - 2)^2$ , and if the oxidation be restricted to the surface atoms, the product will contain  $\frac{x^2 - (x - 2)^2}{4} \text{Ni}_2\text{O}_3$  molecules, and  $\frac{(x - 2)^3}{2} \text{NiO}$  molecules. Since the distance between adjacent Ni and O atoms in the cube is  $2.086 \times 10^{-8}$  cm., the length of the edge of the crystal unit will be  $x \times 2.086 \times 10^{-8}$  cm. By this method it can be shown that 2.5 per cent.  $\text{Ni}_2\text{O}_3$  is formed by the surface oxidation of cubes of  $\text{NiO}$  with edge of about  $55\mu\mu$ , whilst 4.7 per cent.  $\text{Ni}_2\text{O}_3$  corresponds to a cube with edge of about  $30\mu\mu$ . If two surface layers be oxidised, the cubic crystal unit will have an edge twice as long.

It must be pointed out that the size of the crystal unit of  $\text{NiO}$  as determined by this method may not be that existent before the material is heated. It has been found that if the material is finely powdered before heating the amount of  $\text{Ni}_2\text{O}_3$  in the product is rather smaller, and this suggests that during the heating the crystal units tend to increase in size owing to the loss of the adsorbed water.

The adsorption of nickel and cobalt carbonate by pure kieselguhr has also been investigated. The quantitative details will form part of a further communication dealing with the phenomenon of adsorption by kieselguhr, and the salient facts only need be recorded here. When an exactly equivalent amount of  $\text{Na}_2\text{CO}_3$  in dilute solution is added to a suspension of kieselguhr in cold dilute  $\text{Co}(\text{NO}_3)_2$  solution, the cobalt is adsorbed in crystal

units which build up a continuous crystal lattice of  $\text{CoO}$  which is three molecules thick and forms, therefore, a single adsorbed layer of elementary unit cells of  $\text{CoO}$ . This is not the case with nickel nitrate which, on the addition of  $\text{Na}_2\text{CO}_3$  in the presence of 2 per cent.  $\text{KNO}_3$ , appears to be progressively adsorbed in layers of single hydrous molecules of  $\text{NiO}$ . Drying the coated kieselguhr at  $125^\circ$  has no effect unless the surface of the kieselguhr is completely coated with three such layers when the whole deposit condenses to a continuous adsorbed crystal lattice of  $\text{NiO}$  which is three molecules thick, and thus consists of a single adsorbed layer of elementary unit cells of  $\text{NiO}$ .

If the precipitation is carried out at  $100^\circ$ , no adsorption by the kieselguhr takes place with cobalt. In the case of nickel only a very small proportion is adsorbed as the unit cell lattice, the remainder being not adsorbed. It may be concluded, therefore, that at room temperature the units precipitated in the first instance are single hydrous molecules of  $\text{NiO}$  and hydrous elementary unit cells of  $\text{CoO}$ , respectively. At  $100^\circ$  the hydrous units precipitated are larger, too large, indeed, to be adsorbed by the kieselguhr, though in the case of nickel a small proportion exists as hydrous elementary unit cells of  $\text{NiO}$  for a sufficiently long time for them to be adsorbed by the kieselguhr. This conclusion is supported by the fact that it has been proved by the oxidation method that the crystal units of  $\text{NiO}$  are larger in nickel carbonate precipitated at  $100^\circ$  than in the carbonate precipitated at  $15^\circ$ .

Dr. F. Eirich (*Wien*) said: The subject of hydrous oxide gels might be very thoroughly discussed from the point of view of the chemical constitution of the colloid particles and of colloid reactions, but I desire to refer only to one point. Pauli did not conceive colloid particles of this nature to be complex colloidal ions; he explained the preferential adsorption, which is a description rather than a definition of the process as follows: Dissociable molecules of the nature of Werner complexes are supposed to be situated on the surface of the particle, and these determine the course of the reaction. In fact the behaviour of sols is understandable if we compare it with known complex reactions. Indeed the reaction or charge of the particles is profoundly modified by variation or rebuilding of the ionogenic complexes.

The structural formula of iron oxide sols which Professor Weiser criticises was never put forward by Pauli as essentially correct. It merely describes the existence of more or less hydrated hydroxides in the core, and of chlorine ions of dissociated basic chlorides on the surface of the particle.

The pure sol prepared by Pauli and Schmiedt from amalgamated aluminium had a  $p_H$  of 6, so that it is out of the question that hydrochloric acid could take part in the formation of these sols. The increase of the  $p_H$  on adding neutral salt to the sol has been explained in many papers of S. W. Pennycuik (*e.g.*, in the case of platinum sols) as due to hydrolysis of the oxide surface of the particle.

Professor K. H. Meyer (*Genève*) said: Dr. Eirich refers to the old controversy: are the ions on the surface of an inorganic particle fixed by adsorption or by complex-valencies (Pauli). I think one ought not to put the question in this form. The term "adsorption" signifies, or ought to signify, only the place, where an atom or molecule is supposed to be: at a surface or interface, and says nothing as to the forces which link the atom to the surface. These forces can be of any kind: dipole forces, electrostatic attraction, homeopolar forces (so-called activated adsorption), etc. The Pauli-theory only *specifies* the forces of adsorption, which—in many cases—according to this theory should be identical with those which exist in complex compounds.

Dr. J. H. de Boer (*Eindhoven*) said: In connection with the statement of Weiser and Milligan that the precipitates of the oxides consist of agglomerates of minute crystals, it may be of interest to mention the

existence of a special kind of aluminium oxide having half-crystalline properties lying between those of  $\gamma$ - $\text{Al}_2\text{O}_3$  and the amorphous oxide. When aluminium is oxidised electrolytically in oxalic acid or in chromic acid, an amorphous layer of  $\text{Al}_2\text{O}_3$  is formed. It is a porous oxide layer; electrolytes can penetrate it easily. In the air this layer gives a good protection of aluminium and is used as such. When, however, aluminium is oxidised in *e.g.*, boric acid or phosphoric acid an oxide layer of quite different properties is formed. This latter layer has rectifying properties; electrolytes do not penetrate it, only aluminium ions wander through this layer and contribute to the growth of the layer on the outside. As shown by van Geel aluminium can be oxidised first in oxalic acid, where the amorphous layer is formed, and afterwards in boric acid, giving the rectifying layer beneath the amorphous one. The reverse is not possible; if the rectifying layer is made first, oxidation in oxalic acid does not give an amorphous layer under or over the rectifying one, but breaks off the rectifying layer, whereupon the amorphous one is formed free from the rectifying one.

Investigations of Verwey in our laboratory by means of X-rays have shown that the oxygen ions in this rectifying layer form already a crystal lattice but that the aluminium ions are distributed at random through this oxygen lattice. Only after heating the layer to a high temperature is the common  $\gamma$ - $\text{Al}_2\text{O}_3$  formed. We called the oxide of this layer the  $\gamma'$ - $\text{Al}_2\text{O}_3$ , it forms an intermediate state between the amorphous and the crystalline aluminium oxide as it is crystalline with respect to the oxygen, amorphous with respect to the aluminium.

Mr. C. F. Goodeve (*London*) said: Recent measurements which I have made support Dr. Weiser's contention that there is no evidence for the intermediate existence of titanium hydroxide when ammonia is added to a titanate salt. Spectro-photographs of the light scattered from a precipitate less than one second old (a flowing method was used) were found to be practically identical to those of titanium dioxide. On the other hand, there is no resemblance between the spectro-photographs of light scattered from "zinc hydroxide" and zinc oxide. This supports the X-ray evidence which indicates that zinc hydroxide has a definite existence.

Variations in the intensity of the scattered light in the wave-length region of absorption have been found and are interpreted as being due to changes in particle size. It is hoped to apply the method to the determination of the latter in a few favourable cases.

Dr. Weiser's reply is at the end of the volume.

## THE CONDENSATION OF UREA AND FORMALDEHYDE.

By G. WALTER (*Vienna*).

*Received in German on 16th August, 1935, and translated by*  
Dr. E. J. RABINOWITSCH.

Resins, which are generally mixtures of mutually soluble compounds possessing similar structures, can be divided into three groups according to their composition:—

(1) The components are of the same analytical composition and molecular structure, differing only in the length of their molecules (Staudinger's homologous polymers).

(2) The components are of the same composition, but are of different structure (*e.g.* isomers) and molecular size.

(3) All three characteristics—composition, constitution and molecular size—are different.

Urea-formaldehyde resins<sup>1</sup> are known which belong to all these classes; but the majority are of the third and most complicated kind. The differences between the individual resins (and their components) are chiefly due to two factors: *Firstly*, to the different properties of the *primary* products of condensation of urea and formaldehyde at different relative concentrations and under different conditions; and *secondly*, to the different possibilities of further condensation or polymerisation of those primary products. These complications (as well as the insolubility of the end-products) led up to begin the investigation with the study of the conditions under which the different simple products of condensation are formed, and the isolation of these products. In the final part of the paper, the properties of the complicated resins themselves will be discussed.

### I. Conditions under which the Most Important Simple Condensation-Products are Formed.

The **U.F.** condensation-products are either:

(1) *Crystallised substances*—as for instance monomethylol urea (I), dimethylol urea (II), or methylol methylene-urea (III); or

(2) *Amorphous powders*—as for instance methylene-urea  $C_2H_4ON_2$ , or the more highly oxidised product  $C_5H_{10}O_3N_4$ . A. E. Dixon<sup>2</sup> proposed the respective formulæ (IV) and (V) for the last two substances; it will be shown later (see p. 382) that these are incorrect. We shall call these substances Meth A and Meth B;

(3) *Resins*.—The composition of these products is generally complicated and unstable. It will be seen, however, that nearly pure Meth A may sometimes also appear as a resin (composed of polymers and isomers). But in general, the pure methylene ureas give "euthymorphic" products only.

The methylol compounds (I) and (II) alone are primary condensation products; all the other products can be traced back to them.

What products are actually obtained by condensation depends chiefly on the concentration of H ions ( $h$ ), the temperature, and the relative concentrations of the reaction-partners **U** and **F**. In *neutral* or *slightly-alkaline* solutions water-soluble methylol-products are formed at low temperatures. In *acid* solutions, these products are further transformed into the methylene compounds, which are partly insoluble and melt at high temperatures under decomposition. The same products are obtained directly from the initial mixture of **U** and **F** in acid solution. From (I) we obtain Meth A, from (II) Meth B. Nearly pure Meth B is obtained only at high  $h$ -values ( $p_H$  = about 3) or by heating (II) above its melting-point. At low  $h$ 's, **U** and **F** in molecular proportion 1 : 2 give (at high temperature) an opaque resin. If more than three parts of **F** are used, or if dimethylol urea (II) in neutral solution is first formed, then in slightly acid solution completely transparent resins can be obtained:—

<sup>1</sup> The abbreviations: **U** for urea, **F** for formaldehyde will be used throughout this paper.

<sup>2</sup> The literature of the subject can be generally found in a review by G. Walter and M. Gewing, *Kolloid-chem. Beihefte*, 1931, **34**, 163-217; and in the monograph, *Die künstlichen Harze* by J. Scheiber and K. Sandig.

**Low Temperatures:****High Temperatures:**

According to this scheme, the resins are formed under conditions intermediate between those which are suitable for the preparation of the methylol and methylene derivatives respectively, and their composition lies at least partially, midway between that of these products. The first have a simple, well-known constitution; the second require special investigation.

## II. Investigation of the Methylene-Urea-Compounds.

We investigated the *composition*, the *molecular weight*, and the *primary amido-groups* (end-groups) of Meth. A and Meth. B. In connection with these measurements, we also investigated the *electrical conductivity* of these substances (see the following paper) and their *viscosity*.

### 1. Experimental Methods.

**Analysis of the Methylene-Ureas.**—The following method was developed: by heating the substance with  $\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$  in presence of conc. hydrochloric acid, the methylene and methylol groups were transformed into formaldehyde, the nitrogen<sup>2</sup> into ammonia, and the carbon of the CO-groups into carbon dioxide. This method is applicable to all derivatives of urea.

<sup>2</sup> Cf. N determination in urea with  $\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$  after Folin, *Z. physiol. Chemie*, 1901, **32**, 305

**Determination of the Primary Amido-Groups.**—The NH<sub>2</sub>-Groups were determined with the help of conc. hydrochloric acid and sodium nitrite; <sup>4</sup> this method works well with all substances of this class. The volume of N<sub>2</sub> evolved is measured; the reaction must be carried out *without heating*. At a higher temperature, the same method gives the *total* nitrogen-content of the molecule. The concentrated acid causes no undesirable side-reactions, as shown by the values found by analysing the most unstable of all products—the methylol ureas (I) and (II) :

**Determination of the Molecular Weight.**—We found *formic acid* to be an appropriate solvent for methylene ureas and also for a number of U.F-resins. The appreciable conductivity of these solutions shows that all these urea derivatives, not unlike urea itself, are dissolved in formic acid with the production of formates. The measurements of the conductivity have a special interest in connection with the problem of the relations between conductivity and polymerisation, and will be described in full in the next paper. We used the solutions in formic acid, not only for electrolytic investigations, but also for the determination of the *molecular weight*, partly by a cryoscopic method, but mostly by Barger-Rast's method of isothermic distillation. The values of the molecular weights found by this method must be correct owing to their exact conformity with the values found by determination of the NH<sub>2</sub> group. No correction is required in this special case of electrolytic dissociation for directly determined molecular weights, because of molecular association or formation of ionic complexes or micelles which exactly counterbalance the influence of electrolytic dissociation.<sup>4</sup> No appreciable formation of acid amides by reaction of the

<sup>4</sup> Applied to urea by Stanek (see H. Meyer, *Analyse und Konstitutionsermittlung organischer Substanzen*, 1922, p. 938).

<sup>5</sup> Cf. the next paper.

methylene ureas with formic acid takes place at low temperatures and consequently there is no necessity to correct the molecular weight. The change in the apparent molecular weight with time (due to a process of this kind), which is easily observed with urea itself (Table III.) does not occur with its methylene derivatives.

## 2. Investigations of the Fractions of Methylene Urea.

Fractionation was effected simply by spontaneous precipitation of the methylene derivatives at  $p_H = 3$ . We obtained in this way three fractions, (a), (b) and (c); the fourth fraction (d), obtained by evaporation of the last filtrate, was insoluble, and therefore unsuitable for our investigation. Meanwhile, by  $NH_2$  group determination, it was found that the fraction (d) also, although insoluble in formic acid, is low-molecular. Meth A in this respect is like

Meth B trimer.

Consequently, trimers are already insoluble in formic acid, owing to the fact (compare the next paper) that the complexity of ions grows proportionately to the degree of polymerisation.

In the case of the trimer, about 6 urea radicals are already united in the complex. In the case of Meth

B, this fourth fraction was a resin; in that of Meth A, fraction (c) showed—quite unexpectedly—the properties of a resin. All the other fractions were amorphous powders. The analytical compositions of all products—the resins not excluded—were the same, and corresponded to the theoretical compositions of Meth A or Meth B. These results show that U. F resins, formed by methylene ureas, may sometimes have a relatively simple structure (Table IV.).

Table V. contains the experimental values of the molecular weights, the number of  $NH_2$ -groups per mean radical ("  $NH_2$ -number," ) and the molecular weights calculated from these numbers. They are in good agreement with the values found by direct measurement.

Fractions (a), of both Meth A and Meth B, have nearly the theoretical molecular weights of the monomeric substances. The molecular weights of fractions (b) and (c) correspond roughly to those of the dimeric substances.

TABLE V.

d . .	—	25	—	0.34	212	—	0.3	580

\* From NH<sub>2</sub>.

The NH<sub>2</sub>-number is 1 for the monomeric products, and 0.5 for the dimeric ones, etc. This leads to the following formulæ:

(VI) (Meth A monomeric): H<sub>2</sub>N . CO . N=CH<sub>2</sub>.

(VII) (Meth A dimeric): H<sub>2</sub>N . CO . NH . CH<sub>2</sub> . NH . CO . N=CH<sub>2</sub>.

(VIII) (Meth B monomeric):

Dixon's formulæ must be wrong, because they contain no primary NH<sub>2</sub>-groups. Formula (VIII) shows no methylol groups; in fact, no properties pointing to the existence of these groups have been observed with Meth B.

### The Significance of the Molecular Weights.

Despite the relatively low molecular weight values, none of these compounds can be melted; they decompose at temperatures above 200° C. The correctness of the molecular weights seems to be ensured by the accordance between the values found by direct measurement and those calculated from the NH<sub>2</sub>-numbers. The first fractions, (a), must thus be considered as monomeric. The values found for the other fractions can at first be taken as mean values only, and the question then arises whether those fractions contain a certain quantity of substances with a much higher degree of polymerisation; whether such substances may not be responsible for some fractions (fraction (c) of Meth A) showing the properties of a resin.

**Comparative Measurements of Viscosity.**—The occurrence of high polymers may reveal itself by *increased viscosity* more clearly than by a higher mean molecular weight. Experiments showed, however, that all the substances in question, and also various other substituted ureas, have about the same relatively high specific viscosity ( $\eta_{sp}$  in Table VI.). The high viscosity of all these compounds is apparently due to the occurrence of solvated complex positive ions,<sup>6</sup> which they form with formic acid, and has therefore no bearing on our present problem. Nevertheless, the results of the viscosity-measurements seem to indicate

<sup>6</sup> Cf. next paper.

that higher polymerised substances are not contained in fractions (b) and (c).

### 3. Change of the Degree of Polymerisation of Methylene-Ureas by Heating.

These experiments contributed another argument against the presence of highly-polymerised substances in the fractions (b) and (c). They revealed that, by heating the dried methylene ureas, the degree of polymerisation is appreciably increased only in the case of the monomeric fraction. On heating, the molecular weight approaches that of the dimer. The molecular weights of (b) and (c) are changed only very slightly, and only if they were below the dimeric values before heating. The molecular weights of all fractions are thus brought by heating to, or slightly above, that of the dimer (Table VII.). Were the fractions (b) and (c) to consist of a mixture of the monomer with a small quantity of high polymers, we should expect their molecular weights to increase appreciably on heating. This is not the case. We tried to *extract* the

monomer from the mixed fractions (obtained by allowing the solution to stand for a long time, see Table X.), but were unable to prepare products with a much higher molecular weight by this method. (The trimer was the highest obtained in some cases.)

The observation that the monomer can appear in a second, *insoluble* (and probably unpolymersable) form (formula IX) alone suggests that

fractions (*b*) and (*c*) consist of a great deal of the *insoluble* monomer with the inclusion of a small quantity of higher polymers. The higher we assume the degree of polymerisation of this component to be, the lower becomes its possible concentration. By far the greater part of the fraction must then consist of the monomer. The general character of the mixture remains in any case a *low-molecular* one.

It is still more probable that no really high polymers are contained in these fractions, and that the mean molecular weight found experimentally coincides roughly with the true molecular weight of the main component of the mixture (this of course does not exclude the possibility of small quantities of trimers or slightly higher polymers being present).

#### 4. Dependence of the Degree of Polymerisation on the Concentration of H-Ions.

Three solutions of **U** and **F**, with  $p_H = 1, 3$  and  $5$ , were used for the preparation of mixtures of polymers (or isomers) of Meth A. These mixtures (*g*) were divided, by *extracting them with hot water*, into a soluble fraction (*k*) and an insoluble one (*i*). From the most acid solution ( $p_H = 1$ ) the insoluble product was obtained almost exclusively. It consisted of the pure (insoluble!) *monomer* Meth A. At  $p_H = 3$ , the relative quantity of the insoluble residue (*i*) is at its lowest; it consists in equal parts of the dimer and the insoluble monomer. The soluble fraction (*k*)—about 50 per cent. of the total yield—is *monomeric*. At  $p_H = 5$  the insoluble residue contains dimer only, the whole of the monomer being soluble. The soluble fraction *k* even contains some soluble dimer (Tables VIII. and IX.).

TABLE VIII.—MOLECULAR WEIGHT CALCULATED FOR MONOMERIC METH A:  
 $M = 72$ .

$p_H$	Mixture (g).			Residue (i).				Extract (k).			
	NH <sub>2</sub> Number.	M Exp.	M Calc. from NH <sub>2</sub> .	Per Cent. of the Total Mixture.	NH <sub>2</sub> Number.	M Exp.	M Calc. from NH <sub>2</sub> .	Per Cent. of the Total Mixture.	NH <sub>2</sub> Number.	M Exp.	M Calc. from NH <sub>2</sub> .
1	1.0	93	72	98	0.89	84	81	2	1.1	61	65
3	0.96	84	75	50	0.70	111	91	50	1.0	75	72
5	0.65	115	111	67	0.49	140	147	33	0.76	90	95

There exists thus a *soluble* as well as an *insoluble* modification of the monomeric Meth A; the insoluble one is formed at high  $p_H$ -values, and probably has a ring-structure (IX), with one primary NH<sub>2</sub>-group.

With decreasing *h* the soluble fraction increases at the expense of the insoluble one. If the work is carried out under these conditions, the amount of the dimer becomes simultaneously increased at the expense of

TABLE IX.

5	40	60	67	—	~ 67	33	25	8

the monomer, because the soluble monomer alone is polymerisable. On the other hand, by simply letting the solutions stand for some time (keeping the  $p_H$ -value constant) we should increase the amount of the monomer (which polymerises very slowly at low  $p_H$ ) and decrease that of the dimer.

By separating the deposit before evaporating the solution, we found—beginning with  $p_H 3$  and going to lower  $h$ -values—the *second* (polymerising) action of the H-ions. At these low concentrations apparently only very little *insoluble* monomer is formed. The quantity of the primary precipitate (I) (see Table X.) decreases steadily, whereas that of the fraction (Ia), obtained by evaporating the filtrate correspondingly increases.

By extracting with hot water we obtained an insoluble fraction (II) from the precipitate (I); the soluble fraction (IIa) was obtained from the filtrate. With diminishing  $h$  not only does the quantity of (I), but also its relative content of insoluble substances (II), become smaller. *The mean molecular weight of (I) decreases therefore to a certain amount with falling  $h$ .* The molecular weights of (II) are generally appreciably higher than those of (I), and point sometimes to a trimer. The dissolved part (IIa) contains chiefly the monomer, as does the fraction (Ia), which remained in the initial solution.

### 5. Analytical Investigation of the Separate Fractions.

The insoluble residue (II) (see Table X.) differs from all the other fractions of Meth A in that its composition differs from the theoretical composition of Meth A (Table XI.). The smaller values found for N and C indicate the formation of a body (X), which contains ether-like oxygen, similar to Meth B. The analytical results can be explained by assuming a mixture of about equimolecular quantities of Meth A and of the compound (X). This compound can be formed together with Meth A, from two molecules of monomethylol urea, but to an appreciable extent only at higher  $h$ -values. Since the amount of (X) is mostly very small, the methylene ureas A, which have not been further divided into fractions by extraction, show no appreciable deviation from the theoretical composition  $C_2H_4ON_2$ , the peculiar resinous fraction (c) not excluded.

Nearly pure Meth B occurs only (as a precipitate) at high  $h$  values. If  $h$  is less than  $10^{-3}$ , the precipitates have a different composition (Table XI.).

## 6. Relation Between Resinous and Non-Resinous Substances.

All the substances obtained by evaporation of the filtrates of Meth B are *resins* of variable composition. The answer to the question, why some fractions of the methylene products are non-resinous and others resinous is probably that resins are formed only from mixtures containing products of different composition. The existence of resins composed exclusively of *pure* polymers or isomers of methylene urea has never been proved, and appears improbable, especially on account of the discovery of a higher oxygenated Meth A fraction (however small this fraction may be). The least amount of an impurity of this kind may suffice to produce a resin. Probably, certain proportions permitting the mutual dissolution of components are especially favourable for this purpose. The relative concentration of the components determines the character of the precipitate, which may be an eutymorphic powder or a mesomorphic resin. The influence of the relative concentrations of the components, depending in its turn upon the conditions of polymerisation, is also revealed by the fact that mesomorphic resins may have both a higher and a lower mean molecular weight, as compared with that of the eutymorphic fractions. Depending on a greater or smaller quantity of the "stabiliser," which permits the insoluble substances to remain dissolved for a longer or shorter time, their polymerisation can attain a more or less high degree. The molecular weight of the resinous fraction (c) of Meth A lies, for instance, between those of the eutymorphic fractions (b) and (d). It may be, that the *monomer*, also, plays the "stabilising" rôle for the *polymer* (*cf.* p. 389).

The chemical transformations which are necessary for the production of a resin can also be carried out on the already formed Meth B by heating and pressure. It consists in a decrease in the number of  $\text{CH}_2$ -groups, and of the primary  $\text{NH}_2$ -groups, indicating a polymerisation or condensation (Table XII). The resins obtained in this way are, however, mostly opaque.

TABLE XII.

Found for Meth B.	Per Cent. N from $\text{NH}_2$	Per Cent. N Total.	Per Cent. $\text{CH}_2\text{O}$	Per Cent. C from $\text{CO}_2$	Per Cent. C Total.

After pressing	8.63	29.70	35.86	17.45	32.20

In order to obtain resins with high technical qualities, it is obviously necessary to introduce some higher-molecular components. Transparent resins can be obtained from solutions if the reactions leading, at high  $h$ -values, to the eutymorphic Meth B are retarded. Reactions giving Meth B at high  $h$  (for instance  $\text{U} + 2\text{F}$ , or dimethylol urea in acid solution; or melting dry dimethylol urea) all give resins at lower  $h$ . The transformation of dimethylol urea into Meth B is a much slower process than the corresponding reaction  $\text{U} + 2\text{F}$ ; it is therefore advisable to use dimethylol urea for the preparation of the resins (F. Pollak's method). The first stage of the condensation is, therefore, carried out in a slightly alkaline solution, and only the second (resinification proper) in a slightly acid medium. A high concentration of  $\text{H}$ -ions promotes the formation of **F** from methylol ureas (formation of Meth B from dimethylol urea); this action can be paralysed by strongly increasing the

concentration of formaldehyde. Under these conditions, resins can be obtained even in more strongly acid solutions (John).

In order to accelerate the reaction and to increase the solubility, it is necessary to use *high temperatures* and an optimum concentration of H-ions (with dimethylol urea, about  $10^{-4}$ ). Under these conditions, products are formed whose content of "formaldehyde radicals" (methylene, or methylol, or  $\text{CH}_2\text{OCH}_2$  groups) is greater than that of Meth B. They probably contain *methylol groups*; the stabilising and dissolving action of the latter enables the formation of resins and, possibly, the production of higher polymers (see below). For the resinifying reactions we refer again to the scheme given earlier.

### III. Investigation of Complicated Resins.

#### 1. Separation of a Resin-Solution into Fractions (Intermediate Products).

We separated a resin-solution obtained from *dimethylol urea* in slightly acid solution into five fractions (1) to (5). Fraction (1) was deposited spontaneously after long standing; (2) was precipitated from the filtrate by water; (3) was obtained by evaporation of the second filtrate. Fraction (4) we obtained by precipitation with water from the initial solution, and (5) by evaporating the filtrate from (4). In Table XIII. are collected the analytical data obtained with these fractions. We recognise that the fractions (1) and (4), which are deposited from an aqueous solution, have nearly the composition of Meth B, whereas the fractions (3) and (5), which remain dissolved in water, are more similar to methylol methylene-urea (formula (III)); fraction (2) has an intermediate composition. This indicates that the resin is a mixture of substances which are somewhat rich in methylol groups with products containing only few methylol groups or no such groups at all (methylene-ureas). The first are soluble and keep in solution the second, which by themselves are insoluble. By adding water, the concentration of methylol groups is diminished, and the products which are insoluble in pure water precipitated. An opposite effect is observed with highly concentrated *neutral salt solutions*, which have a strongly peptising action.

**Protective Action.**—The above-described experiments show—in accordance with the results obtained with methylene-ureas (see earlier), that resins (at least the intermediate products) contain components which

act as "stabilisers" or "protective colloids" in respect to some other of their components. The "protective" substance is formed simultaneously with the other components. In the case in question, the protective action is obviously due to the methylol compounds; the methylol group  $\text{CH}_2\text{OH}$  acts as a "lyocratic" group.

The protective action not only stabilises the simultaneously formed insoluble methylene compounds, but increases the polymerisation capacity of the protective substance itself as well. The above-mentioned methylol methylene urea (III) can, for instance, polymerise to the compound (XI), and this latter in its turn to ring-systems of the kind (XII) (see below).

The stabilising action of the "protectors" obviously favours the formation of higher polymers, which would otherwise separate from the reacting mixture.

High  $h$ -values cause a decomposition with loss of  $\text{CH}_2\text{O}$  and formation of Meth B, and thus prevent the formation of protective bodies; low  $h$ -values slow down the reaction. Therefore, optimum concentration of H-ions must be maintained, and the reaction must be supported by heating.

## 2. Investigation of the Resinification Reaction.

**Determination of the Water Formed by Condensation.**—Meth B is formed from dry dimethylol urea by heating it, for a long time, above its melting-point. The melted mass becomes acid during the reaction (formation of formic acid). It was found\* (Walter) that by decreasing  $h$  (i.e., by adding alkaline substances) we obtain *resins* instead of Meth B. Water (and some formaldehyde) are formed during the process. Quantitative analysis showed—as a mean value—the production of 1.4 mol. water and 0.2 mol. formaldehyde per urea radical. By melting pure dimethylol urea (without alkaline substances) we obtain 1 mol.  $\text{H}_2\text{O}$  and 0.5 mol. formaldehyde, in accordance with the formula of Meth B (Table XIV). Melting of monomethylol urea gives Meth A under all conditions. From the " $\text{H}_2\text{O}$ -number" 1.4 we may conclude that,

TABLE XIV.

**Determination of the Primary NH<sub>2</sub> Groups in Different Stages of the Resinification Process.**—The determination of the number of primary NH<sub>2</sub> groups in the resins in question does not give so definite a clue to the nature and number of the end groups, as is possible in the case of the methylene-ureas A and B. The formation of formaldehyde (as described above) and the analytical determination of CH<sub>2</sub> groups both showed that the end product does not contain much less than 2 formaldehyde radicals (methylene and methylol groups) per urea-radical (thus corresponding, *e.g.*, to the schemes (XI) to (XIII)); consequently, practically no primary NH<sub>2</sub> groups will be present. In determining the amido-groups in three fractions of resins, corresponding to subsequent stages of condensation of dimethylol urea, we unexpectedly found that in the initial stages (II) and (III), a large number of primary NH<sub>2</sub> groups were present, although there were no such groups in the dimethylol-urea (I) itself (Table XVI.).

TABLE XVI.

	(IV)	0.0	29.2	51.9	11.9	32.7	—
Meth B	—	(10.1)	32.2	51.8	13.8	34.5	—
Dimethylene-urea	—	(0.0)	33.3	71.5	14.3	42.9	—
Resin No. 2	—	0.0	30.2	52.3	12.2	33.5	400
Resin No. 3	—	0.0	20.0	53.3	13.2	34.4	—

This result can be explained by assuming some components of the resin-mixture to have structures of the kind (X) or of the kind of Meth B, with ether-like oxygen (formula (XIV)).

The resin-forming process leads further to a disappearance of the NH<sub>2</sub>-groups, probably by linking (XIV) with other methylene, or

methylol compounds; the fraction (IV) in Table XVI., which corresponds to the end-product, and also the resins Nos. 2 and 3, contained no longer primary  $\text{NH}_2$ -groups.

A direct determination of the molecular weight of resin No. 2 in formic acid gave only 400 as average value (Table XVI.). This relatively low result, which corresponds to a mean order of polymerisation not higher than about 5, does not exclude the existence of a certain proportion of much higher polymers. The products of higher technical value, which probably contain more highly polymerised components, are generally insoluble (without decomposition) in formic acid and in any other solvent. It is therefore impossible directly to determine their molecular weight. Formic acid is the only solvent which dissolves at least the low-molecular resins apparently by forming formates.

**Composition and Structure of the Resins.**—The above-described results show that these resins are much more complicated in structure than those which consist chiefly of polymers or isomers of Meth A or Meth B. They are mixtures of compounds containing little with compounds containing much oxygen; the latter probably include the groups  $\text{CH}_2 \cdot \text{O}$ ,  $\text{CH}_2$  or  $\text{CH}_2\text{OH}$ ; they may also contain tightly bound  $\text{H}_2\text{O}$ . Table XVI. shows the analytical composition of a number of such resins, in nearly the "final" state. Other resins have, however, a different composition; the only general rule is that the composition lies between that of dimethyl urea and that of Meth B and/or dimethylene urea. From the data corresponding to the stages (I) to (IV) in Table XVI. one sees that (II) still has the composition, but not the structure, of the initial dimethylol urea; in (III) and (IV) the N- and C-values became gradually higher, so that the composition of (IV) only slightly differs from that of Meth B. The resemblance is, however, only superficial; the determination of the water and formaldehyde losses during condensation indicate that, in the resins, the content of formaldehyde-radicals must be much higher, and the polymerisation must have proceeded much further than in Meth B. The increase of N and C is obviously due to the greater loss of water and smaller loss of formaldehyde than to the formation of Meth B.

With progressing formation of resin, the substance gradually loses its methylol groups (which have by now fulfilled their protective action), for instance by rings-formation from several molecules (XI). The most important components of the final, insoluble and infusible product are *polymeric dimethylene ureas*. The product contains, however, all kinds of their isomers, more highly oxygenated substances (e.g. XI or XIV) and other related compounds, as well as Meth A and Meth B.

The occurrence of *ring-systems* in resins is proved; open chains can form (if they are present at all) only a part of the resinous mixture, stabilised by them as a solid solution. It can be supposed that not only one-dimensional "ring-chains" of the kind (XII), but also net-like compounds (e.g., XIII) are formed in the course of condensation and present in the final product, especially in the technically important resins.

As to the *size of the molecules*, it was proved that *some F.U. resins* have a relatively low molecular weight. In spite of their low degree of polymerisation the pure methylene ureas (the monomere too!) as well as the resins are infusible and only slight, if at all, soluble in water. The formation of ionic complexes or micelles in acid solution (see the paper "Ionic Complexes of Polymeric Compounds") indicate

that, in the solid products also, the lowly polymerised components are united to micelles. *By the formation of micelles and/or ring-systems the products obtain the character of insoluble and infusible substances.* Of course, it is also possible that certain U.F. resins attain a higher mean degree of polymerisation which, however, has not been proved.

#### IV. Observations as to the Reaction Mechanism.

The later a fraction of methylene ureas is deposited spontaneously from the solution, the higher is, generally, the average molecular weight of the precipitate (*cf.* fractions (a) to (d) in Table V.). These results indicate that the polymerisation proceeds *by stages*.

##### Formation of Ions in Acid Solution of Methylene Compounds.

—By adding sodium hydroxide to a clear aqueous solution of the methylene-compounds the latter are *at once* precipitated from the solution; only in slightly acid solutions do they remain dissolved for some time. (Under ordinary conditions the solution is always slightly acid, due to the formation of formic acid from formaldehyde.) This indicates the formation of small quantities of *formates* from methylene urea and formic acid; on addition of alkali the unstable base is freed and decomposes quickly with precipitation of Meth A or Meth B. This assumption involves the maintenance in solution of a large number of insoluble neutral molecules, bound to a complex by one single ionogenic molecule. This is what actually occurs, according to Wo. Pauli, with the so-called "electrocratic" colloids. We intend to investigate this question more closely, although the instability of the solutions makes it rather difficult.

Quite different are the relations in the case of *resin-solutions* (prepared, for instance, from dimethylol urea). They are *stabilised* in alkaline solutions. The methylene ureas have obviously an electro-positive character; this assumption agrees well with the formation of formates in absolute formic acid, proved by measurements of electric conductivity. The resins appear to be amphoteric compounds, because acid methylol-groups are present in their molecules. During the resinisation-reaction, the negative methylol ureas are gradually transformed, with loss of methylol groups, first into an amphoteric intermediate form (resins), then into an electro-positive methylene derivative. The resins occupy thus an intermediate position between the methylol and the methylene-compounds, not only in relation to the conditions of their formation and their composition, but also in their electrochemical properties.

The rôle played by the acid in the polymerisation-process seems, however, to be based on a linking different from that in the formates. In studying the change of the concentration of H-ions during the polymerisation of dimethylol urea we found indications of the acid being bound by the reacting substances. The measurements are not very reliable, because of the inhomogeneities occurring in the mixture. The *h*-values are found to decrease in the first stage of condensation, but later to increase again, and finally to approach their initial magnitude. The increase of *h* in the later stage is probably due not to the original acid being set free again, but rather to the formation of fresh formic acid from formaldehyde (Table XVII.). The minimum of *h* corresponds to the longest time the solution remains clear; *before* this point amorphous, *after* that resinous deposits are precipitated on cooling.

TABLE XVII.—VALUES OF  $k \times 10^3$ .

Condensation: Duration in Minutes.	0.	5.	10.	30.	40.	50.	60.	110.	150.	190.

.. 2	7.1	$\xrightarrow{\hspace{1.5cm}}$						---	---	---
.. 3	0.35	$\xrightarrow{\hspace{1.5cm}}$						0.16	0.37	0.36

Following A. E. Dixon, we may assume the acid to be bound in a way similar to that in which it is bound in the esters. In this case, the scheme of polymerisation would be as follows:

If the acid is freed *intramolecularly*, we obtain the monomeric (soluble or insoluble) form; if it is freed *intermolecularly*, we get polymers. The actual direction of the process depends on the initial  $k$ -value. The polymerisation by heating of the dry methylene ureas can also probably proceed without the catalytic action of an acid (formic acid).

### Summary.

The U.F.-resins contain generally components of different composition, structure and molecular weight. Their mode of formation, and their composition are both intermediate between those of the easily soluble, crystalline *methylol* compounds and of the nearly insoluble, amorphous powders of the *methylene* compounds of urea. We first describe the properties of the methylene-ureas  $\text{C}_2\text{H}_4\text{ON}_2$  (Meth A) and the higher oxygenated  $\text{C}_6\text{H}_{10}\text{O}_2\text{N}_4$  (Meth B), and study the properties of the complicated resins themselves.

With *methylene-compounds*, we have determined the molecular weight (in formic acid), and the primary amido-groups (as end-groups): both methods gave identical results as to the molecular size. For the determination of the elementary composition a simple method was evolved, which is based on heating with magnesium-chloride. The dissolution of the methylene-compounds in formic acid was found to be accompanied by formation of ionic complexes or micelles.

By fractionation, we separated a *monomer*. Further fractions contained polymers, but with a comparatively low average molecular weight (dimers or trimers). These fractions are not mixtures of the monomer with more highly polymerised substances. The last fractions, which are insoluble in formic acid, contain trimers.

The high specific viscosities in formic acid are similar to those of all other urea-derivatives, and are probably influenced chiefly by the complexity of ions.

Formulæ are proposed for the constitution of the compounds, Meth A and Meth B. The monomer contains one, the dimer  $\frac{1}{2}$   $\text{NH}_2$ -group per urea-radical.

Meth A exists in two forms, soluble and the insoluble; the latter probably has a ring-structure, and is the main product at higher concentrations of the H-ions ( $p_H = 1$ ).

The *methylene-compounds* appear not only as "euthymorphic" powders, but also as "mesomorphic" resins. By fractionating Meth A we have been able to obtain a small fraction having the composition of pure Meth A and the molecular weight of a dimer, with the properties of a resin. Of the fractions of Meth B, the last is always resinous. One fraction of Meth A contains—usually to a very small extent—a different compound, with more oxygen, being probably bound in an ether-like manner. The methylene-urea prepared by the ordinary method is therefore not completely homogeneous. Similar results were obtained with Meth B.

With decreasing concentration of H-ions the yield of euthymorphic methylene-urea deposits becomes smaller. If the proportion 1U per 2F is maintained, resins appear instead. All reactions leading to Meth B at high H-ion-concentrations, yield resins under conditions which slow the reaction down; these are more complicated than those formed from Meth A or Meth B.

By fractionating them, we obtained soluble fractions, which contain more oxygen (methylol groups), and insoluble fractions with less oxygen. The former act as "stabilisers" or "protective colloids," keeping the latter in solution. Dilution with water counteracts the protective action and precipitates the insoluble components of the mixture. An opposite effect is caused by concentrated saline solutions.

The determination of water lost during the condensation indicates the formation of ring-systems. From the amount of alkaline metals absorbed it is concluded that one methylol group (or one mol. of tightly bound water) is present per two urea radical.

In the course of resinification of dimethylol-urea, the resin becomes poorer in oxygen and approaches the composition of a polymeric dimethylene-urea. The composition of the end product lies midway between those of dimethylol urea and of Meth B and/or dimethylene-urea.

The linking of the monomeric molecules either correspond to true polymerisation or involves condensation as well.

The precipitation of the methylene-compounds by alkalis indicates the existence of ionic complexes determined directly by another method.

The methylol group possessing properties of a weak acid, the resins with properties intermediate between those of methylene and of methylol-ureas, can be generally expected to be amphoteric.

The polymerisation appears to proceed in steps. Acid disappears at the beginning of the process, and reappears to the end of it.

In spite of their low degree of polymerisation the products, by the formation of micelles and/or ring-systems, attain the character of insoluble and infusible substances. Of course, it is also possible that certain U.F. resins attain a higher mean degree of polymerisation, but this has not been proved.

# IONIC COMPLEXES OF POLYMERIC COMPOUNDS.

BY GEORG WALTER, *Vienna.*

*Received in German the 9th September, 1935.*

Translated by Dr. E. Rabinowitsch.

During the investigation of the urea-formaldehyde condensation (described in the foregoing paper) we established the structures and determined the molecular weights of two methylene-derivatives of urea,  $C_2H_4ON_2$  ("Meth A") and  $C_2H_4O_2N_2$  ("Meth B"), especially of the first one. By determining the primary  $NH_2$ -groups (by means of nitrous acid), and by measuring the molecular weight (using both the cryoscopic method and that of Barger-Rast) we found that Meth A and Meth B both form *polymers*, containing primary  $NH_2$ -groups on one end of the molecule. We therefore proposed the following formulæ for the three polymeric forms of Meth A:

I.  $H_2N \cdot CO \cdot N = CH_2$ . II.  $H_2N \cdot CO \cdot NH \cdot CH_2 \cdot HN \cdot CO \cdot N = CH_2$ .  
 III.  $H_2N \cdot CO \cdot NH \cdot CH_2 \cdot HN \cdot CO \cdot NH \cdot CH_2 \cdot HN \cdot CO \cdot N = CH_2$ .

Table I. shows that the degrees of polymerisation  $P_1$ , calculated from the determination of  $\text{NH}_2$ -groups, agree well with those,  $P_2$ , found by direct measurement of the molecular weight of Meth A dissolved in absolute formic acid. A large number of fractions (only a part of which are included in Table I.) were prepared either by spontaneous deposition, by polymerisation by heat, or by extraction with hot water. Table I. shows that the degree of polymerisation of all these products is somewhat low. The trimer is seldom attained; most fractions give values lying between those of the monomer and the dimer. It was possible to prepare the monomer and the dimer, although probably not yet in a perfectly pure state.

Despite the practical identity of the molecular weights calculated from the  $\text{NH}_2$  determination with those found by direct measurement, the results became somewhat doubtful when it was discovered that solutions of methylene-urea in formic acid have a marked electric conductivity. This must be due to the formation of salts (formates). In Fig. 1 the conductivities are plotted against the square root of concentration for urea itself and for a number of its derivatives, containing one or several methyl-, phenyl-, or methylol-groups. The concentrations are expressed by the number of mols of urea-radicals per litre. The methylol compounds are related genetically to the methylene ureas, the four curves in Fig. 1 illustrate the electrolytic behaviour of the last substances in monomeric and dimeric form.

Fig. 1 clearly shows the influence of the substituents upon the conductivity.

The following rules hold: "positive" groups (e.g. methyl) increase the conductivity (as compared with that of urea itself); "negative" substituents decrease it. A second substituent of the same sign enhances the action of the first; substituents with different signs mutually weaken their influence. Methylene and methylol are both "negative" substituents, thus resembling phenyl. Methylol ( $-\text{CH}_2\text{OH}$ ) has the strongest influence; methylene (in the form of  $-\text{N}:\text{CH}_2$  or  $-\text{HN}:\text{CH}_2-\text{NH}-$ ) comes next, phenyl last. The position held by methylol in this series is due to its slightly acid character. An analogous explanation must be given for the fact that the Meth B-curves lie generally below those of Meth A: the first compound contains relatively more oxygen, probably because of the occurrence of a  $\text{CH}_2\text{OCH}_2$  group (or of a  $\text{CH}_2\text{OH}$ -group) in its molecule. The higher conductivity of the dimers as compared with the monomers will be discussed below.<sup>1</sup>

<sup>1</sup> The monomer is marked a, the dimer with c.

In the second column of Table I., are collected the equivalent conductivities  $\lambda$  of the single fractions of Meth A. The numbers given are those found for 0.1 *N* solutions (urea radicals being treated as divalent). From these data, we may calculate the corrections which must be applied to the values  $P_2$  or  $P_1$ , in order to take account of the electrolytical dissociation (the degree of dissociation  $\alpha$  is about 15 per cent. at this concentration.<sup>2</sup>) In the case of polymerising ions, even a relatively small dissociation may cause an important correction, which becomes greater with increasing  $P_1$ . Table I. shows that the re-calculated (apparent) degree of polymerisation

$P_2 = \frac{P_1}{1 - 2\alpha P_1}$  is 1.5 instead of 1 in the case of the "monomer" of Meth A (exp. 1), and as much as 6 (instead of 2) in the case of the "dimer" of the same substance (exps. 7 and 8).<sup>3</sup>

If the newly calculated polymerisation-degrees  $P_2$  were to be considered as the real ones, then the  $\text{NH}_2$ -determination must be wrong and the accordance of its results with those of the direct measurement of molecular weight a pure coincidence. Two arguments support the assumption that this is not the case: (1) The observation that the above-mentioned coincidence occurs in *all* cases; and (2) The fact that the  $\text{NH}_2$ -method was found to give satisfactory results in the case of the methylol compounds of urea, which, although related to the methylene-compounds, are much less stable than the latter. No danger exists, therefore, of error due to decomposition of Meth A and formation of formaldehyde during the measurements.<sup>4</sup> The degrees of polymerisation  $P_1$  obtained by the  $\text{NH}_2$  method (identical with the values  $P_2$ ) must therefore be explained in a different way. The explanation may be the formation of *ionic complexes*. The complexes must be ions, and not associations of neutral molecules, because only the assumption of complex ions can reconcile the degrees of polymerisations  $P_1$  and  $P_2$  with the conductivity measurements. We must assume that the formation of complexes counterbalances exactly the increase in the number of particles due to electrolytic dissociation.

If the particles linked in this way to the original ions are themselves ionised, then the degree of complexity  $K_1$  (which is only a mean value, like the degree of polymerisation  $P$ ) can be calculated by means of the formula

$$K_1 = \frac{P_2}{P_1} = \frac{1}{1 - 2\alpha P_1}$$

(or, for Meth B,  $K_1 = 1/(1 - 4\alpha P_1)$ ). For the dimers of Meth A (exps. 7 and 8),  $K_1$  is in the neighbourhood of 3, for the dimers of Meth B (exp. 13) it is about 6. On the other hand, we may assume the particles linked to the primary ion in the complex to be neutral molecules. In this case, the degree of complexity would be  $K_1 = 1 + 2\alpha P_1$ . The values  $K_1$  are generally smaller than  $K_2$ . Moreover, they increase with increasing  $P_1$ . For the dimer of Meth A,  $K_1$  is approximately 2 (Table I.). By multiplication of  $K_1$  (or  $K_2$ ) by  $P_1$ , we obtain the number of urea radicals in one (polyvalent) ion—a number including both the degree of polymerisation and the degree of complexity.

In making the calculations, we assumed the ions to have either the valency  $2P_1K_1$  or (in the case of neutral partners forming the complex) the valency  $2P_1$ . We further assumed the value  $\lambda_\infty = 60$ , which was found experimentally for other formates dissolved in formic acid. We disregarded the diminution of the  $\lambda_\infty$ -value which may be due to the greater

<sup>2</sup> The molecular weights were determined at this same concentration; they change, however, only very slightly with concentration. The value of  $\alpha$  was calculated by putting  $\lambda_\infty = 60$  (see further below).

<sup>3</sup> Meth A is taken as divalent; the corresponding equation for the tetra-valent Meth B is  $P_2 = P_1/(1 - 4\alpha P_1)$ . The numbers found for the monomeric and the dimeric fraction are printed in italics in Table I.

<sup>4</sup> A decomposition of this kind could produce new  $\text{NH}_2$ -end groups; in this case the  $P_1$ -values found would be too small.

size of the particles, caused by polymerisation as well as by formation of complexes. As shown by Fig. 2, the equivalent conductivities  $\lambda$  of the methylene ureas increase slowly even at the highest dilutions; it is therefore impossible to determine  $\lambda_{\infty}$  by graphical extrapolation.

This slow increase of  $\lambda$  and of  $\alpha$ , as well as the small absolute values of these magnitudes, must be due to the presence of complexes, which are well known to cause phenomena of this kind. In Table I. we gave the equivalent conductivities  $\lambda$  (calculated for 1 mol. urea-radicals per 2 litres) for 0.1 *N* solutions of different methylene urea fractions. By assuming monovalency of the monomer, and calculating the equivalent conductivity for 1 urea-radical per litre ( $\lambda_{gm.}$ ), (still using the value 60 for  $\lambda_{\infty}$ ) we still obtain numbers which are much smaller than these found, for instance, for sodium formate in formic acid. Table II. shows that sodium formate is almost completely dissociated already at a dilution  $v = 4.9$ . In the case of the monomer Meth A, however, this dilution corresponds to a degree of dissociation of not more than 20 per cent. (not more than 10 per cent., if we assume divalency and  $\lambda_{\infty} = 60$ , giving together  $\mu_{\infty} = 120$ ). In Fig. 2 the conductivities  $\lambda_{gm.}$  (calculated for 1 mol of urea per litre, irrespective of the degree of polymerisation) are plotted against the square root of the concentration. We recognise a slow increase of  $\lambda_{gm.}$ , which continues even at the lowest concentrations, thus pointing towards a gradual "activation" of all possible valencies of the molecule.

This behaviour suggests that the particles which lead to the formation of the complex ion are neutral molecules; it is therefore probable

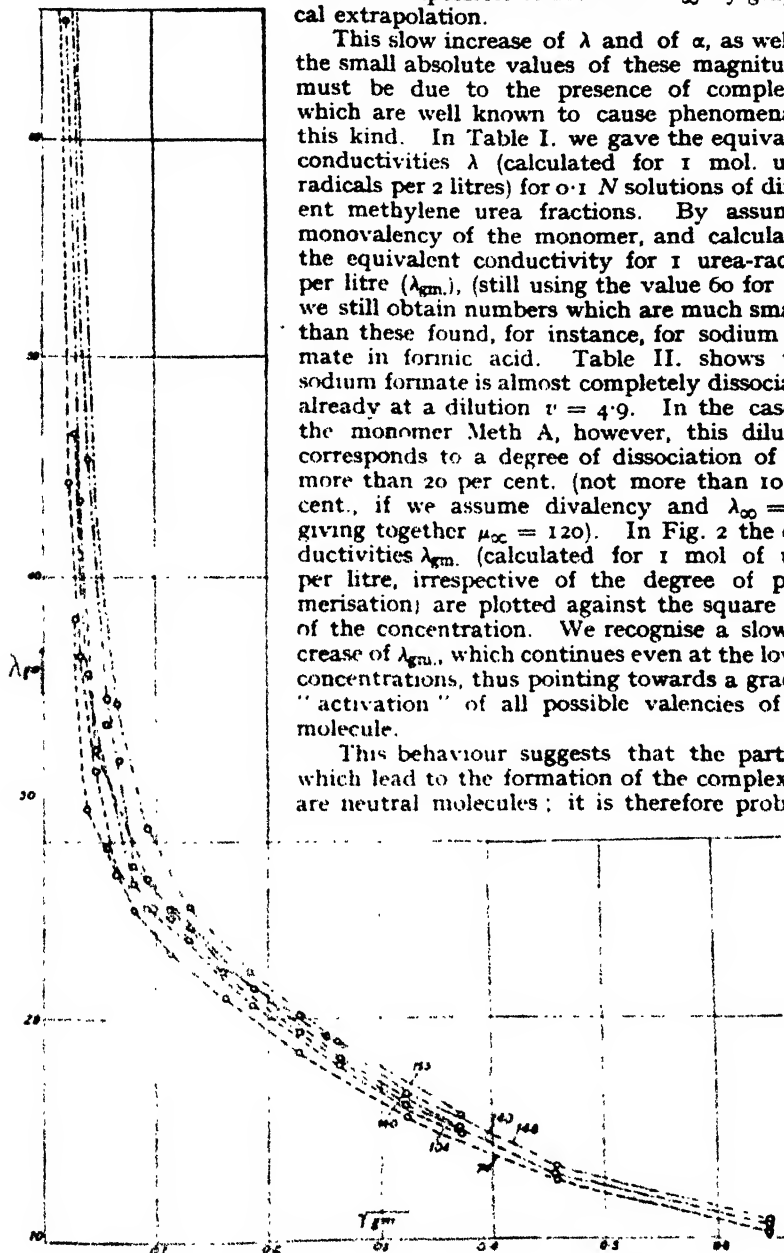

FIG. 2.

that the smaller  $K_1$  values have a more real meaning than the  $K_2$  values. It is, however, to be kept in mind, that the  $K_1$  values also increase with increasing degree of polymerisation; in cases of high polymerisation (although

not in the one we are now concerned with) they may obtain quite considerable values.

Fig. 2 shows further that the equivalent conductivity generally increases with the molecular weight and degree of polymerisation  $P_1$ . On Fig. 2 are indicated the corresponding molecular weights; the upper curves are those with the highest molecular weights. It is not improbable, that this increase is due—at least partially—to the changes in the substitution of  $NH_2$ -groups which are concerned with polymerisation (the combination

FIG. 3.

$H_2N + N : CH_3$  being transformed into  $HN \cdot CH_3 \cdot NH \cdot$ ; see above). An analogous connection exists between the specific viscosity and the degree of polymerisation (Fig. 3). The parallelity between the specific viscosity and the equivalent conductivity, as well as the high absolute values of the former, may be connected with the complexity of the ions. The viscosity is of the same order as that of the others (non-polymerising) derivatives of urea (cf. this vol., p. 383, Table VI.).

The shape of the curves showing equivalent conductivity as a function of dilution is, however, somewhat different in the case of urea (or the methylene ureas) and that of the methylene ureas. Fig. 4 shows that the curve for urea approaches a constant limit which is not very different from  $\lambda_{\infty} = 60$ . Since the concentrations are measured by the number of urea-molecules per litre, this result indicates the monovalency of urea ions, since the value  $\lambda_{\infty} = 60$  was found for monovalent ions. (Our previous arguments are, however, not changed in principle by the assumption of monovalency. The values of  $\alpha$  are to be doubled, and the equation for  $K_2$  becomes  $K_2 = 1 + \alpha P_1$ ). Symmetrical diphenyl-urea and symmetrical dimethyl diphenyl-urea show some resemblance with the methylene-ureas inasmuch as their  $\lambda_{\text{gm.}}$ -values are relatively much smaller.\*

The average structure of the methylene-urea complexes is illustrated by formula (IV). (The free charges are not shown.)  $P_1$  indicates the degree of polymerisation,  $K_1$  the degree of complexity, and  $R$  an acid radical.

The methylene-compounds of urea are closely connected with the urea formaldehyde resins (*cf.* this vol., p. 377). Since the polymerisations leading to the formation of resins are also catalysed by acids (usually by formic acid), it is not impossible that ionic complexes may play a rôle in this process, in which higher polymers are surely involved. Already, with  $P_1 = 5$ , we obtain from  $K_2 = 1 + 2\alpha P_1$ ,  $K_2 P_1 = 55$  (at this high dilution,  $\alpha$  must be equal to 1). The formation of complex ions cannot change the mean degree of polymerisation, the quantity of acid present being very small in comparison with that of urea. It would seem possible that the acid may catalyse not only the ordinary polymerisation process, but also the formation of complexes, in the following way: First, the acid ion associates itself with a neutral molecule; this charged system attracts more molecules and a complex ion is formed. Finally, the acid ion leaves the complex (if only to associate itself with some other particles). The remaining neutral complex may hold together, even after the loss of the charge.

### Summary.

The comparison of electrical conductivities of monomeric and polymeric methylene-ureas in formic acid with the results of the direct determination

\* Meanwhile it has been stated that all ureas, too, form complex ions in formic acid, also to an extent that the influence of electrolytic dissociation is counterbalanced.

of the molecular weights in the same solvent, as well as with those of the determination of primary  $\text{NH}_2$ -end-groups shows that ionic complexes must be present in these solutions.

In the formation of complexes the increase in the number of particles due to electrolytical dissociation is always exactly counterbalanced by the decrease due to the production of complexes. Direct determinations of molecular weight give therefore results which show no signs of electrolytical dissociation. Only from the results of all three methods together—determination of the end-groups, conductivity and molecular weight—is it possible to show the formation of complexes. The equivalent conductivity varies with the degree of polymerisation and with the nature of the substituents in the amido group. The influence of positive and negative substituents has been examined. In formic acid all ureas give complex ions.

The degree of complexity increases with growing polymerisation. The complexity can, however, obtain remarkable values even at very low polymerisations under certain conditions.

The formation of complex ions makes the equivalent conductivity of the methylene urea formates appear low as compared with that of other formates.

As a hypothesis, it is suggested that in the formation of *resins* from urea and formaldehyde the formation of ionic complexes or micelles (in slightly acid solution) plays a certain rôle additional to ordinary polymerisations.

---

## CONDITIONS UNDER WHICH INSOLUBLE AND INFUSIBLE RESINS ARE PRODUCED, ESPECIALLY THOSE FORMED BY ARYL-SULPHAMIDE AND FORMALDEHYDE.

BY GEORG WALTER, *Vienna*.

*Received in German, 9th September, 1935, and translated by  
Dr. E. Rabinowitch.*

The aryl-sulphamides offer a very convenient example for the investigation of the conditions under which soluble or insoluble, fusible or infusible resins are produced. By simply changing the number and/or the nature of the substituents ( $\text{SO}_2\text{NH}_2$ ) in the benzene ring it is possible to change the properties of the resins formed by condensation of the sulphamide with formaldehyde. This problem, moreover, has a technical interest: resins which, by continued polymerisation or condensation, finally become insoluble and infusible (a process known as "hardening") are of special technical importance. Important examples are the so-called phenoplasts and aminoplasts. The latter include the urea formaldehyde resins.

The condensation of phenols or amides with formaldehyde can be considered as a two-stage process. (1) The *primary condensation* of phenol or amide with aldehyde, giving a "primary condensation product," and (2) the further condensation or polymerisation of the primary product. Process (1) leads to the formation of a product containing methylol groups ( $\text{CH}_2\text{OH}$ ). (These groups substitute for instance an H-atom in the benzene ring of phenol or in the  $\text{NH}_2$  group of the amide). The methylol group can bring about further polymerisation in two ways: either by intermolecular dehydration, as in (2a), or by intramolecular loss of water, followed by a combination of two dehydrated molecules

—as in (2b). Both may lead to the formation of one and the same condensation product:

In order to link together more than two molecules, the basic molecule (phenol or amide) must contain at least two active-atoms. In the case of phenol, aromatic H atoms in appropriate position in the ring may play this rôle; in the case of the amides, those of the  $NH_2$ -group.<sup>1</sup> To enable the formation of a doubly bound methylene group, as in (2b), the two reacting H atoms must be near each other.

Until recently, only soluble and fusible resins were known belonging to the aryl sulphamide class. They were obtained, for instance, by condensation of *p*-toluene sulphamide with formaldehyde. We found that by introduction into the molecule of a second group capable of reacting with formaldehyde, e.g., another  $SO_2NH_2$ , or  $CONH_2$ , or simply  $NH_2$ , it is possible to obtain *insoluble* and *infusible* resins, which can be hardened.

Products of this kind were prepared for instance from *m*-benzene di-sulphamide, from 1, 3, 5-benzene trisulphamide, from *meta*- and *para*-sulphamide benzamide, from the aniline sulphamides, etc. Analogous results were obtained in the series of naphthalene sulphamides: The mono-sulphamides produced soluble, the di- and tri-sulphamides insoluble resins.<sup>2</sup>

These experiments lead us to the general conclusion,<sup>3</sup> that in order to obtain hardened resins, it is necessary to use substances with more than one active group in the molecule.

*Exceptions* to this rule (i.e., cases in which, despite the presence of two active groups, no insoluble resins can be obtained) occur either when one of the two groups does not react with aldehyde, or when the product of this primary reaction is in some way inhibited from further polymerisation. The first phenomenon sometimes is due to too great an accumulation of substituents, so that the reactivity is so much decreased that the polysulphamides do not react with aldehydes at all. Acetaldehyde forms condensation products with the aniline mono-sulphamides, but not with the corresponding di- and triamides. The same observation was made on some crystallisable products: Benzaldehyde reacts, for instance, with the monosulphamides (giving benzyldene derivatives) but not with polysulphamides. The *ortho*-position

<sup>1</sup> "Bifunctional" groups, as defined by Carothers.

<sup>2</sup> Details may be found in the papers by G. Walter and collaborators, *Kolloid-chem. Beihfte*, 1933, 37, 343 and 1934, 40, 1.

<sup>3</sup> Cf. the dissertation by A. Glück, Univ. of Vienna, 1930. The same rules, based on different experimental materials, were since enounced by other authors as well; cf. further the systematic investigations by Carothers.

of two substituents may also sometimes inhibit reaction. Aniline *o*-sulphamide gives with acetaldehyde only a *mono*-ethylidene compound, whereas the corresponding *meta* and *para*-sulphamides form di-ethylidene derivatives.

In the second case, both groups take part in the formation of the primary condensation product, but despite this fact only soluble and fusible resins are formed as final products. In this case again the *ortho*-position of the substituents accounts for the failure to polymerise. Aniline *o*-sulphamide forms, for instance, only fusible resins, although both groups take part in the primary reaction and produce a dimethylene compound as primary condensation product. The corresponding *meta* and *para* compounds give *methylene-methylol* derivatives as primary condensation products, which are able to polymerise further, until the products become insoluble and infusible.

It is thus proved that *steric hindrance* is responsible for the deviations from the rule.

Table I. shows some of the substances investigated, together with the end-products of their condensation. We investigated the condensation of aryl sulphamides, of the aryl sulphamide-carboxamides, and finally of the aniline sulphamides, with different aldehydes. Where the condensation products are pure methylene compounds, the formulae in the Table give the true elements of the structure forming the polymer. In the cases of more complicated polymers (which are generally methylol methylene compounds) the formulae give only an approximate idea of the average composition of the resins. So far, neither the exact position of the single substituents, nor the molecular size of these "hardening" resins has been definitely established.

The structure of resins which are formed by the mono-sulphamides was established with a fair degree of certainty (p. 406).

The increase in the number of groups has a double effect. *Firstly*, it increases the number of different possible reactions, and thus leads to a greater variety of polymerisation products—a result favourable to the formation of resins. *Secondly*, it favours the possibility of chain formation, thus favouring the formation of insoluble and infusible products. If one active group alone is present, only one-dimensional chains or simple rings can be formed. The presence of two or more active groups involves the possibility of the formation of networks, complicated ring-systems, or even three-dimensional structures. Staudinger's one-dimensional polystyrenes<sup>4</sup> remain soluble and fusible even at a very high stage of polymerisation; the urea formaldehyde resins, being the condensation products of a basic molecule with two active groups, are insoluble and infusible, even at a very low stage of polymerisation. This is the result of the ring-structure of these polymers. The capacity to "harden" is therefore due less to a high degree of polymerisation than to the formation of ring-systems,—more to the *constitution* and less to the *molecular size*. Incidentally, the insolubility of "hardening" polymers is, in itself, one of the causes which prevents them from growing further.

<sup>4</sup> The above discussed rule enabled us to expect divinyl-benzene to yield "hardening" resins. This prediction was confirmed by Staudinger's experiments.

\* Cases of an especially quick and easy "hardening" are marked by two crosses.

### Constitution of the Aryl Sulphamide Formaldehyde-resins.

The results will be discussed here only briefly. The aryl monosulphamide formaldehyde resins are transformed by the action of alcoholic hydrochloric acid, as well as by simple heating, into a mixture of crystallisable dimethylene and trimethylene compound (I.) and (II.). These compounds are insoluble in potassium hydroxide, which

TABLE II.

Substance.	Molecular Weight Measured in Phenol (Mean).	Molecular Weight Calculated.
Resin from <i>o</i> -toluene- monosulphamide .	400	—
Component compound (III.) . . . . .	545	567
Transformation pro- duct (I.) . . . . .	370	366
Transformation pro- duct (II.) . . . . .	530	549

easily dissolves the resin itself. They must therefore possess a ring structure. The main component of the resin itself is probably the methylene methylol compound (III.), which yields (I.) by decomposition (together with free sulphamide and formaldehyde), and (II.) by simple dehydration. The compound (III.) was obtained in a crystallisable

form by treating the resin with formic acid. Further, a methylene disulphamide (IV.) was obtained from the resin by extraction with benzene. The structure of all these compounds was established by analysis and determination of molecular weight (see Table II.); their percentage in the resin was determined as well.

The "hardened" (insoluble and infusible) resin obtained from *m*-benzene disulphamide contains polymers of the dimethylene *m*-benzene disulphamide (*cf.* Table I.). Crystallisable products were isolated from a number of hardened resins; we found them to contain  $\text{CH}_2$ -groups linked in many different ways. (The naphthalene disulphamide formaldehyde resins contain, *e.g.*, a  $\text{CH}_2 \cdot \text{O} \cdot \text{CH}_2$  group (*cf.* Table I.).)

### Summary.

As a result of investigations of the condensation products of the aryl mono- and poly-sulphamides, of the amides of the aryl sulphamido-carboxamides and of the aniline sulphamides, it was observed that the presence of more than one active group (*i.e.*, in the case in question, of more than one primary amido-group) is necessary for the formation of insoluble and infusible resins.

Exceptions occur from steric hindrance (by too copious substitution), and in the cases of *ortho*-substitution which inhibit the primary reaction of the amide with the aldehyde, or diminish the polymerising capacity of the primary condensation product. In Table I., the results of a large number of substances were investigated and rough formulæ given for the average condensation products.

The aryl-monosulphamide-formaldehyde resins were found to contain (or to yield) certain crystallised dimolecular and trimolecular methylene compounds. A number of aryl disulphamide formaldehyde resins were found to contain polymeric dimethylene compounds. Some others are more complicated mixtures, containing methylene and methylol methylene compounds.

The properties of insolubility and infusibility were found to be due chiefly to an appropriate *constitution* (formation of complicated ring-systems, made possible by the presence of two or more "bi-functional" groups in the basic substance), and much less to a high degree of polymerisation.

### GENERAL DISCUSSION.

**Dr. F. C. Wood** (*Manchester*) said: It is interesting to find the author has suggested the ether linkage  $-\text{CH}_2 \cdot \text{O} \cdot \text{CH}_2$  to his Methylene Urea B which Mr. A. E. Battye and I found to occur in the condensation product of unsymmetrical dimethyl sulphamide and formaldehyde giving

The difficulty in investigating the highly insoluble urea formaldehyde resin compounds seems to indicate that a study of the sulphuryl diamide formaldehyde resin would give further clues to the structure of this type of condensation. I emphasise that the clue to the linkage of the type

came very easily from a brief study of a condensation of dimethyl sulphamide and formaldehyde, which was confirmed by Walter's work later with the sulphonamides, and therefore it is perhaps reasonable to suppose that the more soluble sulphuryl diamide formaldehyde resin would be more amenable to investigations on molecular structure and complexity.

**Professor K. H. Meyer** (*Genève*) said: I think one ought to consider the reactions between urea and formaldehyde from a more general standpoint, without introducing specific formulæ. If urea reacts with a limited quantity of aldehyde, one can obtain the so-called methylene urea described by Dixon.<sup>6</sup> This product, described by Walter as amorphous, shows, as Hemmi and Pankow found in Geneva, crystalline interferences. In its solubility it resembles the higher polypeptides of glycine. That is why we assume that it is a somewhat high molecular polymer of the simple and regular formula

In the presence of an excess of formaldehyde, one obtains water-soluble, highly viscous polymers, described by John.<sup>6</sup> We admit that the solubility

<sup>6</sup> *J. Chem. Soc.*, 1918, 113, 238.

<sup>6</sup> *Oestr. Patent*, Nr. 78251, 1918.

In its typical form—as in natural rubber, slightly vulcanised gutta-percha, hydrocarbon polychloroprene, thiokol—we find substances which have an elastic and (approximately) reversible extensibility, permitting an elongation of 300, 500, or even more than 700 per cent. Moreover, these substances are all characterised by the typical form of their stress-strain curves; by the development of heat (Joule-heat) on stretching; by “crystallisation” and by formation of fibre structure, when stretched. In this form I have described the typical phenomenon in my book, published in German in 1934.

Now I do not see that Dr. Houwink has sufficiently proved that any of his three substances: asphalt, glass and the B-state of phenol-formaldehyde resins is a rubber-like substance in the sense of my definition. On the other hand, I recognise with sincere appreciation the value of Dr. Houwink's researches on the large elastic extensibility of his resins in the B-state. I hope he will investigate how far those other properties are present which I consider as characteristic for real rubber-like extensibility. Let us not forget that there are a number of “rubber-like” substances which do not show some of the characteristic qualities, or show them only in a weakened degree. For instance, isoprene-heat-polymerisate has not shown “crystallisation” on stretching; yet it develops a certain amount of heat and a certain amount of fibre structure when stretched. It would be very interesting, if Dr. Houwink would compare such substances with the B-resins mentioned above, and see if perhaps these uncharacteristic poor “rubber-like” substances stand half-way between real rubber and B-resins.

Dr. Carothers' doubt, whether the crystallinity of high polymeric substances is a real crystallinity raises a problem which seemed very difficult to answer when, first, X-ray spectrography was applied to substances of this kind, and which, in the case of rubber, is even now not entirely clear to me. I myself questioned whether the “crystallisation” of rubber, when stretched, is a real crystallisation; I gave expression to this doubt when writing my first publication about the phenomenon<sup>42</sup> and even questioned whether we may not have to do with a new type of substances, which I called pseudo-crystalline-amorphous ones. The structure of a liquid under 20,000 atmospheres pressure (when it retains a certain amount of plasticity under this high pressure) is the closest comparison. The molecules can be forced into a three-dimensional arrangement, without being *entirely* comparable with a real crystal. In the case of rubber the form of the molecule—a long thread—may be particularly favourable for the development of such a state; as the threads are straightened by extension, they are pressed laterally against one another, so that the fundamental units of the molecules are forced into the closest possible packing.

On the other hand, we must admit that, after twelve years during which X-ray spectrographical research, all the facts have proved more and more explicable by the hypothesis that where there is a crystalline X-ray pattern, we have to do with real crystals; with a new phase in the sense of the phase rule. In the case of rubber, however, I admit that the clear *discontinuity* in the anisotropy curve (see Fig. 6) at the critical elongation suggests clearly—together with the X-ray data—that we have to do with a real change from an amorphous into a crystalline phase. Studying the influence of temperature on this critical elongation, Professor Ornstein (Utrecht) has even been able to apply the Clapeyron equation to it. In the case of crystalline phases which can only exist under very high pressures (several of the “ices,” for instance) their equilibrium conditions are governed by the phase rule; which seems to indicate clearly that they are real crystalline phases.

<sup>42</sup> *Naturwissenschaften* 1925, 13, 411.

I soon hope to publish about rubber-like vulcanised gutta-percha hydrocarbon and its analogy with natural rubber.

I now come to the very important question raised both by Professor Kurt H. Meyer and Professor H. Mark: *what degree of certainty can be attached to their calculations of the crystalline lattice of high polymeric substances and of the position of the molecules therein.* These calculations in 1928 gave a great impetus to our understanding of the high polymeric substances and at that time provided one of the strong arguments for the long chain molecule. All agree that their work had the merit of putting us on the right track. But we are now in 1935, and I think it is surprising that no one has *investigated, as impartially as possible, to what extent their arguments of 1928 were convincing, and to what extent there is ground for doubt.*

Professor Mark admits uncertainty, but he says that we may attribute to these models "a somewhat high degree of truth." And he agrees with me that we must improve these ideas here and there, and that more or less important changes may have to be made; although he states, too, that in his opinion the present point of view will not have been entirely changed when the full solution is found. On this point I agree a good deal with him.

Professor Meyer believes that when he uses thin films in which there is not only a parallel orientation of the crystals in one direction, but also an orientation in the plane perpendicular to this axis, one can calculate with *certainty* the three periods of identity and the elementary cell. The same thesis was defended by an author who reviewed my book in *Z. Elektrochemie*, 1935. In my opinion, both authors are wrong in making this statement. They might have been right, if the X-ray interferences of the high molecular weight substances were very sharp (like those of NaCl, CaCO<sub>3</sub>, etc.). But with the lack of sharpness of the interferences, as observed in cellulose, silk fibroin and all such substances, we never can exclude the possibility that what we consider as one interference may be made up from more than one. Moreover the orientation is often not so perfect as we would desire. These uncertainties affect the calculation of the elementary cell. Moreover all interferences with an angle of deviation  $\theta$  larger than 30°-40° are completely absent, which excludes the possibility of control by higher orders of reflection; I regret the other authors mentioned do not agree with my reservation, which seems so plain to me.

Both Professor Meyer and Professor Mark emphasise that the certainty of their special models arises not only from the X-ray data, but also because the conclusions drawn from them are strengthened by chemical evidence. I am unable, however, to rate the degree of certainty they have reached as highly as they do.

I wish chiefly to emphasise the need of work which does not try merely to confirm or to attack their point of view, but which seeks an impartial discussion of the following points:—

(a) Description and measurement of all the interferences observed; how far are we certain that *all* the interferences have been found; that they are not conglomerates of more than one interference; that they are not due to continuous radiation; what "doubled interferences" mean, etc.

(b) Checking of this information by oblique exposures; and by exposures in different directions of films showing orientation in more than one direction; careful discussion on the relative uncertainty of all the factors involved.

(c) Calculation of the elementary cells; *how many* and *which different* solutions accord with all the facts mentioned under (a) and (b); *which* solution is preferable and *why*; which conclusions can be drawn from chemical or analogous evidence, and their relative cogency compared with evidence drawn from only X-ray data.

(d) Accurate measurement of the relative intensities (in pure monochromatic light) of all the interferences observed. The old rule that the relative position of atoms in the elementary cell requires necessarily such intensity measurements should not be given up in the more difficult case of high polymeric substances.

(e) The position of the molecules within the elementary cell. Chemical and analogous evidence will be needed for a good estimate. Other possible solutions should, however, be discussed, and compared with the intensity measurements, with the chemical evidence, etc.; and the relative probability of the different solutions should be made clear.

Meantime we should seek to prevent the presentation, in elementary text-books and in biological, biochemical or technical literature, of merely probable solutions, as though they were as good as proven. In every scientific subject there are three typical phases of development. In the first one collects interesting facts and seeks to co-ordinate them; in the second one possible explanation of the whole mass of facts is presented; in the third we have several such explanations, and by an *experimentum crucis* can make a choice between them, which is to be considered as a certainty. The whole subject I have discussed above is really only somewhat fully developed into the second stage; whilst it is more and more quoted as being in the third stage. It is against this exaggeration of certainty that I have felt it my duty to warn you.

If preliminary, and still uncertain solutions of the problem are so presented they may be very useful for the growth of the subject. But they should be so presented or quoted and with that degree of uncertainty.

**Professor Medvedev**, in reply (see page 296) (*communicated*) the opinion of Bergmann,\* that the polymerisation of 1, 3-butadiene† takes place by way of a mono-sodium compound, can hardly be concordant with the observed results without a special strained interpretation. The supposed mono-sodium compounds of Bergmann of the type:

are evidently not stable, and cannot exist for long as free radicals.

In the case of an artificial stoppage of the reaction (*e.g.*, evacuation of the butadiene during polymerisation in the gaseous phase) these radicals would dimerise or be subjected to some other transformation, and the renewal of the process would not be possible. However, our experiments show that interruption, even for many hours, of the polymerisation process does not show a marked change in the kinetics of the process. Formation of the mono-sodium compound was used by Schlenk to explain the appearance of dimerisation by the action of the alkali metals on non-symmetrical substituted ethylene. On the other hand, Ziegler<sup>7</sup> showed that, by the action of sodium or lithium on 2, 3-di-methyl butadiene and the decomposition of the formed products by water, tetra-methyl ethylene is formed; this is a very substantial argument in favour of the formation of di-sodium compounds.

It is extremely possible that the major part of the polymerisation process takes its course by means of a chain mechanism in the same sense as was formulated in the discussion by Rideal and Mark. Polymerisation of di-ene hydrocarbons in the presence of the alkali metals, however, is a particular case, which differs in the fact that the growth of the polymerising molecule takes place as the result of a series of reactions in which the union of the monomer to the stable sodium-organic compound occurs. This monomer is probably activated in the process of "solution" in the polymer.

One of the results of the stability of the intermediate products ("active centres") is the circumstance that the reaction "chain" does not break and the polymerisation process, after the attainment of a stationary stage, proceeds with a constant rate for an indefinitely long time in spite of the fact of interruptions.

**Dr. H. B. Welser** (Houston, Texas), in reply (see page 377) said: It is interesting to note that Pauli never considered the formula

\* Bergmann builds his scheme on the example of di-methyl butadiene, but we studied the polymerisation of 1, 3-butadiene.

† *Lieb. Annalen* 511, p. 64, 1934.

for a ferric oxide sol as essentially correct. The trouble is that this and similar formulas for other oxide sols have been repeated and copied so many times in both text-books and papers by Pauli and others, that most people think that Pauli believes them to be essentially correct. Indeed, last year at the General Discussion on Colloidal Electrolytes before the Faraday Society, the neutral part and the charged ionic group of a ferric oxide sol are given by Pauli as  $\text{Fe}(\text{OH})_3$  and  $\text{FeOCl}$ , respectively. Since  $\text{Fe}(\text{OH})_3$  has not been prepared and  $\text{FeOCl}$  is formed only under special conditions at high temperatures, we may be reasonably sure that neither is present in the sol as ordinarily prepared. It is not obvious what is gained by assuming the presence of an ionogenic complex such as  $\text{FeOCl}$  on the surface of the sol particles when ferric chloride and hydrochloric acid, which are known to be present, will serve equally well as stabilising electrolytes for the sol. Just because the  $p_H$  value of an oxide sol is 6, it does not follow, as Dr. Eirich believes, that hydrochloric acid cannot be the stabilising electrolyte in such a sol. As a matter of fact, the  $p_H$  value of the sol would be 7 if all the stabilising hydrogen ions were adsorbed on the surface of the particles. It is probable that the stabilising electrolyte in Pauli and Schmidt's sol formed in the presence of dilute aluminum chloride is largely the latter salt rather than hydrochloric acid. There is no apparent justification for assuming that the stabilising electrolyte is a basic salt such as  $\text{AlOCl}$  whose existence in the sol or elsewhere has not been established. Since the neutral part of the oxide sols formed in the presence of chloride contain more or less of the latter element, the constitution is represented by some point in the three-component diagram

This does not mean that the sol contains free hydrochloric acid.

In Pennycuik's platinum sols to which Dr. Eirich refers, the contra ion is hydrogen ion, just as in ferric oxide and alumina sols the contra ion is usually chloride ion. When neutral salts are added to platinum sols an exchange adsorption takes place between the cation of the added salt and the hydrogen ion. This causes the  $p_H$  value of the sol to decrease rather than to increase. The acidic oxide on the surface of the particles causes hydrolytic cleavage of some salts, the base combining with the acidic oxide. This process likewise tends to decrease rather than to increase the  $p_H$  value of the sol.

# A METHOD OF ANALYSIS OF HEAVY WATER.

BY ADALBERT FARKAS.

*Communicated by* ERIC K. RIDEAL.

*Received 13th November, 1935.*

Whilst several methods<sup>1</sup> are available for the analysis of heavy water, the micro-thermo-conductivity method<sup>2, 3</sup> is so convenient for the analysis of hydrogen-deuterium mixtures that it seemed desirable to attempt an application of this technique to heavy and ordinary water without involving the decomposition on a hot tungsten wire.<sup>3</sup> The method is based upon the following principles.

If water containing  $W_D$  per cent. D be brought into equilibrium with its own vapour and with hydrogen, these will contain respectively  $V_D$  per cent. and  $G_D$  per cent. deuterium.<sup>4</sup> We denote by  $f$  the ratio of the vapour pressures of  $H_2O$  and  $D_2O$  and  $K_3$  the equilibrium constant of the reaction

$$\text{i.e.,} \quad K_3 = \frac{[HDO][H_2]}{[H_2O][HD]}.$$

Then

$$V_D = \frac{W_D}{100 - W_D f + W_D} \quad \frac{G_D}{100 - G_D} = K_3 \frac{W_D}{100 - W_D},$$

if we assume<sup>4</sup> that the equilibrium constants of the reactions

are  $K_1 = K_2 = 4$ .

If the liquid water be maintained at 20° C. and equilibrium in the gas phase be established on a hot platinum wire at 1000° K. we obtain the following D-contents for the hydrogen in equilibrium with water of different D-contents.

According to Lewis and Macdonald<sup>5</sup>  $f = 1.15$  at 293° K.  $K_3$  has

<sup>1</sup> A. Farkas, *Parahydrogen, Orthohydrogen and Heavy Hydrogen*, the Cambridge University Press, 1935.

not yet been determined accurately at  $1000^{\circ}\text{K}$ .; extrapolation from the equilibrium measurements <sup>4, 6</sup> gives us the value 1.1.

TABLE I.

D-content of the Water ( $W_D$ ), in Per Cent.	D-content of the Vapour ( $V_D$ ), in Per Cent.	D-content of the Gas ( $G_D$ ), in Per Cent.
0	0.0	0.0
25	22.5	20.9
50	46.5	44.1
75	72.4	70.5
100	100.0	100.0

Thus we can easily calculate from the D-content of the gas in equilibrium (under the given conditions) with the water to be analysed the unknown D-content of the latter.

The experimental arrangement is shown in Fig. 1.

The cell is 10 cms. long and 5 mm. in diameter. After having placed about

0.1-0.2 c.cm. of water in tube A, the cell is exhausted and hydrogen (or deuterium) introduced at about 10 mm. Hg and then the spiral is heated. By means of the capillary lock L from time to time small samples of gas are extracted and their D-content analysed by the micro-thermo-conductivity method. Table II. shows the results obtained with different samples of heavy water of known D-content (determined by density measurements).

It will be noted that the final value is reached within a few minutes and is independent of whether we start with pure hydrogen (experiment 3) or with deuterium (experiment 4). The experimental figures for the equilibrium D-content are in satisfactory agreement with the calculated values (column 5), the average error being 1.5 per cent. The accuracy of the measurement might be affected by the following sources of error: the cell is not absolutely dry (from previous experiment), the water contains gases (including such as, *e.g.*, HCl) or evaporable organic compounds which can be decomposed by the hot filament, there is too little water available for the analysis (see below). On the other hand substances (whether present dissolved or undissolved) which have no appreciable vapour pressure, or the hydrogen dissolved in the platinum wire, do not influence the accuracy of the analysis.

The minimum quantity of water required for a determination is limited by the total amount of hydrogen admitted. The D-content of the water will not change appreciably if the equivalents of water and hydrogen present are in the ratio 500:1 (1 mg. water being equivalent approximately to 1 c.c. of  $\text{H}_2$ , N.T.P.). In this particular cell 0.2 c.c. of  $\text{H}_2$ , N.T.P. (or  $\text{D}_2$ ) were introduced and at least 0.1 g. of water was used for each measurement. It is, however, a simple matter to reduce this quantity to 0.01 g. by using 1.5 c.c. cell (*e.g.*, 4 mm. diameter and 5 cms. long). The accuracy of the analysis can be increased by empirical calibration.

The present method of analysis is specially suitable for investigating the interchange of hydrogen and deuterium atoms between water and other substances (provided the latter have no appreciable vapour pressure) without the need of separating the water for each determination. It possesses advantages if only small amounts of water are available (*e.g.*,

in biochemical problems) or if a series of analyses have to be made when other methods would take too much time.

The following experiment may be cited as an example for the application of the present method. 1.032 g.  $\text{NH}_4\text{NO}_3$  were dissolved at  $20^\circ\text{C}$ . in 0.5 c.c. of 29.5 per cent. heavy water. The D-content of the solution was found to be 15.5 per cent.

Since 1.032 g. of  $\text{NH}_4\text{NO}_3$  are equivalent to 0.465 g. or 0.466 c.c. water the D-content of the ammonium nitrate ( $S_D$ ) was

$$\frac{(29.5 - 15.5)0.50}{0.466} = 15.0 \text{ per cent.},$$

i.e., practically the same as that of the water. Consequently the quantity  $\frac{W_D(100 - S_D)}{S_D(100 - W_D)}$  is practically 1.

This result is in agreement with the earlier experiments of Bonhoeffer and Brown,<sup>7</sup> who obtained a value for the system  $\text{NH}_4\text{Cl}/\text{H}_2\text{O}$  of 1.25 which they regarded as too high.

### Summary.

Description of a method for the analysis of heavy water based on an exchange reaction with hydrogen.

The author is very much indebted to Professor E. K. Rideal, F.R.S., for his interest in these experiments and to the Imperial Chemical Industries Ltd. for financial assistance.

*Laboratory of Colloid Science,  
Cambridge.*

\* This determination was made a few months ago. The actual D-content was probably slightly less owing to manipulations with the water.

# THE CATALYTIC INTERACTION OF AMMONIA WITH DEUTERIUM.

BY ADALBERT FARKAS.

Communicated by ERIC K. RIDEAL

Received 13th November, 1935.

In a previous communication <sup>1</sup> an account was given of an exchange reaction between deuterium and ethylene. A number of similar reactions involving organic substances have since been investigated.<sup>2</sup> The subject matter of this paper deals with an exchange reaction between ammonia and deuterium which may be written

and which occurs at the surface of an iron catalyst.<sup>3</sup> Apart from it being representative of a new group of exchange reactions it is of interest in connection with the catalytic synthesis of ammonia.

## Experimental.

In previous experiments <sup>4</sup> it was found that even apparently outgassed material contains a certain amount of hydrogen absorbed in such a form as to become apparent by an exchange reaction when brought into contact with deuterium. A catalyst possessing a negligible amount of such occluded gas can be prepared by forming a metallic mirror by evaporation

FIG. 1.

of an iron wire. Such mirrors when deposited at room temperature are readily prepared, reproducible in activity, reasonably active and stable.

The experimental arrangement is shown in Fig. 1. The reaction vessel (12 cms. long and 2 cms. in diameter) contained an axially mounted iron (electrolytic) wire 10 cms. long and 0.2 mm. in diameter arranged with leads in the usual way so as to permit of electric heating. The U-tube U

was cooled to  $-50^{\circ}\text{C}$ . in order to keep tap grease and mercury from poisoning the catalyst. With these precautions the catalyst did not markedly decrease even after a week's use at  $200^{\circ}\text{C}$ .

Before deposition of the catalyst the reaction vessel was thoroughly outgassed in the furnace F at  $350^{\circ}\text{C}$ . (or using Pyrex vessels at  $500^{\circ}\text{C}$ .) the wire was being maintained at  $900^{\circ}\text{C}$ . The furnace was then removed by means of the rollers R and the wire heated to  $1100^{\circ}$ - $1200^{\circ}\text{C}$ . to evaporate the iron. This temperature was maintained (with continuous exhaustion) until a uniform mirror was formed. If the catalyst has once been poisoned (e.g., by admission of air to the reaction vessel) a new catalyst was prepared by evaporating fresh iron in the same vessel. The evaporation process could be repeated four or five times before the wire broke.

In order to obtain more information about the interaction of hydrogen and ammonia on this catalyst, the *ortho-para*-conversion and interaction of hydrogen and of deuterium and the decomposition of ammonia were investigated in addition to the exchange reaction between ammonia and deuterium.

To investigate the exchange reaction and the *ortho-para*-conversion, the micro-thermoconductivity method was employed, ammonia being frozen out in a trap cooled by liquid air.<sup>5</sup> The decomposition of ammonia was determined by extracting samples of gas from the reaction vessel and measuring the pressure caused by this sample after freezing out the ammonia.

The following gases were used: ammonia (purified by fractional distillation *in vacuo*), deuterium (80 to 100 per cent. D), ortho-deuterium<sup>6</sup> (100 per cent. D, prepared by adsorption on charcoal at  $20^{\circ}\text{K}$ . and subsequent evaporation), parahydrogen (prepared in a similar way) and a mixture of hydrogen and deuterium (containing only  $\text{H}_2$  and  $\text{D}_2$  molecules). All gases were free from oxygen, the hydrogens were initially purified by passage through palladium. The pressures of the gases admitted into the reaction vessel were measured by the manometer M (see Fig. 1).

The experiments to be described were carried out partly on the same catalyst, partly on different catalysts.

### The Exchange Reaction between Ammonia and Deuterium.

Since in all experiments the rate of the exchange reaction was determined by measuring the decrease in the D-content of the deuterium originally added special care had to be taken to avoid the following sources of error. The D-content of the deuterium may decrease by an exchange reaction with hydrogen occluded or absorbed by the catalyst or formed by a catalytic decomposition of ammonia taking place on the surface of the catalyst. Separate experiments excluded the former

TABLE I.

Temperature $^{\circ}\text{C}$ .	Previous Treatment of the Catalyst.	Minutes.	Per Cent. D.

		15	2

possibility since—as has already been mentioned—no interchange could be observed with gases occluded by these catalysts. Thus there was only

<sup>5</sup> (a) A. Farkas, *Z. physik. Chem.*, 1933, 22B, 344; (b) A. and L. Farkas, *Proc. Roy. Soc.*, 1934, 144A, 467.

<sup>6</sup> A. Farkas, L. Farkas and P. Harteck, *Proc. Roy. Soc.*, 1934, 144A, 481  
A. and L. Farkas, *ibid.*, 1935, 152A, 124.

a negligible decrease in the D-content of deuterium brought into contact with a catalyst previously exposed to hydrogen and practically no formation of deuterium after the catalyst has been in contact with deuterium (see Table I.).

By experiments on the rate of decomposition of ammonia it was found that in no case could the amount of uncondensable products formed account for more than a small fraction of the decrease in the D-content actually observed. On the same catalyst, for example, as referred to in Table II. at 233° C. and 15 mm. Hg of NH<sub>3</sub>, the amount of uncondensable gas formed was 3 mm. in thirty minutes, *i.e.*, very little in comparison with the rate of the decrease in the D-content (see Table II.).

TABLE II.

234° C., 10 mm. NH<sub>3</sub> + 15 mm. D<sub>2</sub>

Minutes.	D-content in Per Cent.
0	96
0	34
15	23

Fig. 2 shows that the decrease in the D-content is actually due to an exchange. Curve *a* indicates the change in the D-content of 30 mm. deuterium when mixed with 26 mm. NH<sub>3</sub> at 233° C. After thirty minutes the ammonia was frozen out (in trap U, Fig. 1) the deuterium pumped out and 22 mm. of hydrogen added. The flat portion of the curve *b* shows once more that no exchange reaction occurs in the absence of ammonia but sets immediately when the ammonia is evaporated (in the twelfth minute). In this case the D-content of the hydrogen added naturally increases at the expense of the "heavy" ammonia formed in the previous experiment.

FIG. 2.

The equilibrium constant of the reaction <sup>7</sup>

$K = \frac{[\text{NH}_2\text{D}][\text{H}_2]}{[\text{NH}_3][\text{HD}]}$  could not be accurately determined by measuring the final D-content of a mixture of ammonia and deuterium for the following

reason. The value of the equilibrium constant obtained is very sensitive to the final D-content observed and an inaccuracy of a few per cent. in the determination of the final D-content may cause a considerable error in the determination of the

TABLE III.

EQUAL PRESSURES OF D<sub>2</sub> (100 per cent. D) and NH<sub>3</sub>.

Final D-content in Per Cent.	K.	$2K/3 = (\text{H/D})_{\text{A}} \cdot (\text{D/H})_{\text{B}}$
40	1.5	1.0
35	2.1	1.5
30	3.0	2.0

equilibrium constant (see Table III.).

<sup>7</sup> A. Farkas, *J.C.S.* (in the press).

In the third column  $(H/D)_h$  and  $(H/D)_a$  represent the ratio of the H- and D-content in the hydrogen and ammonia respectively.<sup>7</sup> The inaccuracy in the determination of the final D-content is due to the slight decomposition of ammonia (especially the formation of nitrogen). Another source of error is the strong adsorption of ammonia on the glass walls especially on those cooled to low temperatures (U tube), and thus the amount of ammonia taking part in the interchange is actually more than that calculated from the pressure readings. Both sources of error tend to produce a final D-content which is too low or an equilibrium constant which is too high. After allowing for this inaccuracy it was found that the equilibrium is definitely larger than the classical value of  $3/2$  being at  $220^\circ\text{--}230^\circ\text{C}$ . about 2 to 3.\* This provisional result which is in agreement with theoretical calculations requires confirmation by more accurate experiments.<sup>8</sup>

FIG. 3.

In order to exclude any uncertainty in the value of  $K$  the dependence of the rate of the exchange on pressure was investigated in mixtures with excess of ammonia in which the equilibrium D-content is very low.

The progress of the interchange at  $200^\circ\text{--}210^\circ\text{C}$ . at different deuterium pressures and constant ammonia pressures and at different ammonia pressure and constant deuterium pressures is shown in Figs. 3 and 4. It will be seen that whereas the relative rate of the interchange remains

FIG. 4.

unaltered by changing the ammonia pressure, it decreases with increasing deuterium pressure.

In another series of runs the dependence of the rate of interchange was investigated at a varying total pressure

but at approximately the same ratio  $NH_3 : D_2$ , see Table IV.

The measure for the relative rate of the exchange is the time ( $\tau$ , in minutes) in which the original D-content has decreased by 25 per cent. and is given in column 5, whereas the measure for the absolute velocity being proportional to the deuterium pressure and  $1/\tau$  is listed as  $P_{D_2}/\tau$  in

\* Such a value follows indirectly from exchange experiments between heavy water and ammonium salts. (Bonhoeffer and Brown, *Z. physik. Chem.*, 1933, 23B, 171, and A. Farkas, *Trans. Faraday Soc.*, in the press.)

<sup>8</sup> Cf. also K. Wirtz, *Naturwiss.*, 1935, 23, 271.

TABLE IV.

Temperature C.	Pressure of Deuterium in mm. Hg ( $P_{D_2}$ ).	Pressure of Ammonia in mm. Hg ( $P_{NH_3}$ ).	$P_{NH_3}/P_{D_2}$	25 Per Cent. Decrease in the D-content Reached in ( $\tau$ ).	$P_{D_2}/\tau$ .

210	29	228	23 ..	1.26
212	51	243	31 ..	1.64

From Tables IV. and V. we note that the absolute rate of the exchange reaction, *i.e.*, the number of atoms exchanged is practically independent of the ammonia pressure but increases approximately with the square root of the deuterium pressure.

The dependence of the rate of interchange on temperature is shown in

FIG. 5.

Fig. 5 for the temperature region 164°-234° C. and at 15-17 mm. of  $D_2$  and  $NH_3$ . (The curves for 211° and 234° refer to the catalyst in a slightly less active form.)

The apparent energy of activation ( $E$ )

was calculated from the dependence of the rate of exchange on temperature with the equation

$$\frac{d \log 1/\tau}{dT} = \frac{E}{RT^2}$$

$\tau$  denoting the time (in minutes) in which the original D-content has decreased by 25 per cent. (see Table VI.).

### The Ortho-para-conversion.

In a series of previous publications<sup>9</sup> it was shown that the catalytic *ortho-para*-hydrogen conversion on metals involves an atomic mechanism.

It was important to obtain some information about the catalytically active adsorption layer by this method since the "sorptive" capacity of this catalyst was hardly measurable. (There is no necessary connection between adsorptive capacity and catalytic activity. High adsorptive capacity is not always indicative of a high catalytic activity.)

On a fresh catalyst the *ortho-para*-hydrogen conversion occurred at room temperatures and a few mm. Hg pressure at a high velocity equilibrium being established within a few minutes. Under similar condition there was, however, no exchange reaction to be detected even after several hours.

Although it has already been shown that the reactions<sup>10, 16</sup>

proceed on a catalyst by the same mechanism namely by dissociation into atoms, it seemed desirable to show this including also the reaction  $o\text{-D}_2 \rightleftharpoons p\text{-D}_2$  for the catalyst actually employed. Fig. 6 shows the establishment of the equilibrium in these reactions at 10 mm. Hg pressure and 20° C the logarithm of the "distance" from equilibrium ( $u$ ), (taken as 100 at the beginning and 0 at the end), being plotted against the time.

It will be noticed that though the individual reaction rates are different,

FIG. 6.

<sup>9</sup> Bonhoeffer and Farkas, *Z. physik. Chem.*, 1931, 12B, 231; A. Farkas, *ibid.*, 1931, 14B, 371; Bonhoeffer, Farkas and Rummel, *ibid.*, 1933, 21B, 225; Bonhoeffer and Farkas, *Trans. Faraday Soc.*, 1932, 28, 242; A. Farkas, *Ortho-hydrogen, Parahydrogen and Heavy Hydrogen*, The Cambridge University Press, 1935.

the relative rates being 5 : 2 : 1 for  $p\text{-H}_2$ ,  $o\text{-D}_2$  and  $\text{H}_2 + \text{D}_2$  respectively, these three redactions proceed with a very similar speed.

The temperature coefficient for these reactions are likewise very similar, indicating that in these processes practically the same energy of activation

TABLE VII.

Reaction.	Temperature C.	Half-Life Time in Minutes.	Energy of Activation in Kg Cala.

	40	15	

\* Catalyst different.

is involved (see Table VII.). As expected slightly higher values are obtained for the reactions involving deuterium.

We note that this apparent energy of activation is considerably lower than that found for the exchange reaction between deuterium and ammonia. This

difference in the energies of activation is responsible for the fact that the conversion reaction takes place readily at temperatures which are  $200^\circ\text{C}$ . below those necessary for the exchange reaction.

It was found that the presence of ammonia inhibited the conversion of *para*-hydrogen, the inhibiting effect being dependent on the pressure of ammonia. Fig. 7 shows this effect at  $82^\circ$  and  $122^\circ\text{C}$ . and 15 mm. Hg of *para*-hydrogen, the velocity of the conversion in the absence of ammonia being taken as unity. The inhibiting effect at these temperatures is reversible i.e., the original activity is restored as soon as the ammonia is removed.

In spite of this inhibition the conversion reaction is even in the presence of  $\text{NH}_3$  much faster than the exchange as clearly shown by the following experiment.

In the thermo-conductivity cell employed for the analysis of hydrogen and deuterium mixtures hydrogen, normal deuterium and *ortho*-deuterium had the following "resistance" values (i.e., the resistance of the wire in the thermo-conductivity cell when heated in the gas),

FIG. 7.

	$\Omega$ .	$\Delta\Omega$ relative to $n\text{-D}_2$
normal hydrogen ( $n\text{-H}_2$ )	91.70 ohms.	- 12.19 ohms.
normal deuterium ( $n\text{-D}_2$ )	103.91 "	0.00 "
<i>ortho</i> -deuterium ( $o\text{-D}_2$ )	106.39 "	+ 2.48 "

Thus it was easy to show how much more quickly the conversion of *ortho*-deuterium proceeded than the interchange reaction in a mixture of  $o\text{-D}_2 + \text{NH}_3$ .

Fig. 8 shows the progress of these reactions in a mixture of 12 mm.  $o\text{-D}_2 + 15$  mm.  $\text{NH}_3$  over the temperature range  $20^\circ$  to  $155^\circ \text{C}$ ., the differences in the resistance values (relative to  $n\text{-D}_2$ ,  $\Delta\Omega$ ) being plotted as a function of time. At  $155^\circ \text{C}$ . there is slight exchange reaction to be observed proceeding a hundred times more slowly than the conversion; at  $82^\circ \text{C}$ ., however, there is practically no exchange reaction.

Whereas the inhibition of the  $p\text{-H}_2$  conversion is reversible at  $80^\circ \text{C}$ . and upwards, at room temperatures the poisoning effect of ammonia persists even after removal of that gas. When ammonia is admitted to a fresh catalyst there is an immediate formation of some uncondensable

FIG. 8.

gas. Although it was not possible to analyse this gas owing to its small amount ( $2 \cdot 10^{-4}$  c cm. N.T.P.) it was shown that it was formed from the ammonia and not displaced by it from the catalyst in the following way. A newly formed catalyst was brought into contact with deuterium, its activity being measured by the catalytic conversion of  $o\text{-D}_2$ . The gas formed by admitting  $\text{NH}_3$  was mixed with sufficient (100 per cent.)  $\text{D}_2$  in order to obtain  $4 \cdot 10^{-2}$  c.cm. (N.T.P.) of gas which was the minimum amount necessary for one measurement in the thermo-conductivity cell. The D-content of this sample was found to be 96 per cent. showing that the gas formed was not deuterium displaced by the ammonia from the catalyst. In the thermo-conductivity cell the resistance values for  $\text{H}_2$  and  $\text{N}_2$  are approximately equal and therefore it was not possible to decide whether the defect of 4 per cent. D was due to the presence of  $\text{H}_2$  alone or to a mixture of  $\text{H}_2 + \text{N}_2$ . The poisoning effect is shown in Table VIII.

### Discussion.

We assume that this reaction is taking place between molecules adsorbed on the surface of the catalyst. As far as the ammonia is concerned this assumption is justified by the strong adsorption which causes the inhibiting effect of the *para-ortho*-conversion and the independence of the rate of the exchange reaction on the ammonia pressure. On the other hand from previous experiments <sup>9,10</sup> we know that the *ortho-para*-interconversion likewise takes place in the adsorption layer, and from the following it will be seen that there is a connection between the conversion and the exchange reactions.

We can examine the following two reaction mechanisms <sup>2</sup> making the further assumption that no transport processes between the gaseous phase and adsorption layer affect the actual reaction rate.

- Mechanism I. (a)  $D_2 = D + D$   
 (b)  $D + NH_3 = (NH_3D) = NH_2D + H$   
 (c)  $H + D = HD.$
- Mechanism II. (a)  $D_2 = D + D$   
 (b)  $NH_3 = NH_2 + H$   
 (c)  $NH_2 + D = NH_2D$   
 (d)  $H + D = HD.$

Mechanism I. is the heterogeneous analogue to the mechanism involved in the thermal interaction between NH<sub>3</sub> and D<sub>2</sub> occurring at 600° C. and upwards in the gaseous phase.<sup>7</sup>

In both mechanisms the activation of the deuterium is common. If the activation of the deuterium consists in dissociation (or at least in loosening the bond between the deuterium atoms) the *ortho-para*-conversion gives us a measure of this step since every dissociation and recombination process is necessarily connected with conversion. Actually it is found that the conversion reaction proceeds very much more quickly than the exchange reaction indicating clearly that II. (a) and (d) and I. (a) and (c) are not the rate determining steps. The dependence of the reaction rate on pressure suggests that neither is II. (b) rate determining since this reaction could not be accelerated by increasing D<sub>2</sub> pressure.

Thus we come to the conclusion that either the exchange reaction I. (b)

or the recombination reaction II. (c)

is the rate determining step depending whether mechanism I. or II. is valid. This is an interesting result since it shows that we have the same dependence of the rate of exchange on the pressure of  $\text{NH}_3$  and  $\text{D}_2$  (provided the ammonia is strongly adsorbed) whether ammonia is completely dissociated or not and that the kinetics of this reaction is compatible with both mechanisms.

Thus our problem reduces to enquiring how the ammonia is adsorbed.

Even at room temperatures a slight evolution of gas is observed when ammonia is brought into contact with a fresh iron surface. This cannot be due to a slow decomposition of ammonia into  $\text{N}_2$  and  $\text{H}_2$  since the formation of gas is only observed with a fresh catalyst and stops suddenly. It is more probably due to a reaction  $\text{NH}_3 = \text{NH}_2 + \text{H}$  in which the radical  $\text{NH}_2$  remains on the catalyst whereas the hydrogen is given up into the gas phase. This behaviour was actually observed by Frankenburger and Hodler,<sup>11</sup> who were able to show that on admitting ammonia to tungsten powder at  $90^\circ \text{C}$ . only hydrogen is evolved. It is also well known that at  $500^\circ \text{C}$ . nitride formation occurs which is not restricted to the surface of the iron but proceeds into the bulk phase. The formation of nitride and its reduction by hydrogen were demonstrated experimentally by Dünwald and Wagner.<sup>12</sup> Finally the experiments of Winter<sup>13</sup> on the catalytic decomposition of ammonia on iron show definitely that the rate determining step is the decomposition of the nitride indicating that loosening of  $\text{N}-\text{H}$  bonds takes place before the nitride is decomposed.

The experimental evidence justifies the assumption that on the surface of the catalyst at  $200^\circ \text{C}$ . a large fraction of the ammonia is dissociated\* and makes it probable that for the exchange reaction mechanism II. is responsible.

Thus we can form the following picture of the interaction of ammonia with deuterium (or hydrogen) on the catalyst.

In the absence of ammonia, hydrogen or deuterium are very easily dissociated on the catalyst as shown by the low activation energy for the conversion (8.9 kg. cal.). The conversion involves not only the dissociation process but also a migration of the hydrogen atoms since it is found that  $\text{H}_2 + \text{D}_2 = 2\text{HD}$  reaction proceeds with a similar speed when compared with the conversion.†

If ammonia is added the greater part of the surface is covered cutting down the area accessible to hydrogen. At  $20^\circ \text{C}$ . a part of the ammonia covering the surface is decomposed into amide and hydrogen and the

<sup>11</sup> (a) Frankenburger and Hodler, *Trans. Faraday Soc.*, 1932, **28**, 229; (b) Frankenburger, *Z. Elektrochemie*, 1933, **39**, 45, 97, 269.

<sup>12</sup> Dünwald and Wagner, *Z. physik. Chem.*, 1934, **24B**, 53; Engelhardt and Wagner, *ibid.*, 1932, **18B**, 369.

<sup>13</sup> Winter, *Z. physik. Chem.*, 1931, **13B**, 401.

\* Whether the dissociation of ammonia proceeds according to  $\text{NH}_3 \rightarrow \text{NH} + \text{H}_2$ ,  $\text{NH}_3 \rightarrow \text{NH} + \text{H}$ ,  $\text{NH} \rightarrow \text{N} + \text{H}$ , and to what an extent these processes occur we cannot infer.

† It will be noticed, however, that the rate for the reaction  $\text{H}_2 + \text{D}_2$  does not lie between that for the *ortho-para*-conversion of hydrogen and deuterium but is slower than either reactions. This effect (if not due to some impurity) might suggest that the migration involves a slightly larger energy of activation than the dissociation but in any case this difference is negligible being less than 1 k. cal.

hydrogen leaves the surface. The irreversibility of the inhibiting effect of ammonia is due either to a strong adsorption or to this surface amide formation, the hydrogen not being able to reduce the surface amide at these low temperatures. At higher temperatures (100° C.) the surface amide becomes reducible and the inhibition by ammonia becomes reversible. This reduction occurring according to

is the same reaction as the rate determining step in our mechanism II. of the exchange reaction. The actual exchange reaction however only becomes observable if the reduction proceeds with a very great speed as shown by the following example. Let us assume 1 cm.<sup>2</sup> of active surface in contact with 10<sup>20</sup> molecules of a mixture of D<sub>2</sub> and NH<sub>3</sub> (10<sup>20</sup> molecules are contained in 50 c.c. at 50 mm. Hg pressure). If the reduction of the 10<sup>15</sup> molecules covering the surface of the catalyst takes place in one second the exchange reaction would require 10<sup>5</sup> seconds. Thus the poisoning effect over this temperature range is due to the formation of the surface amide which also explains the fact why the *ortho-para*-conversion is not inhibited at higher pressures of ammonia. Through the dissociation process one part of the surface (namely that occupied originally by the third H-atom of the NH<sub>3</sub>) remains always accessible to the hydrogen. A similar explanation might be advanced to explain the fact that no displacement of deuterium by ammonia is observed. (Cf. Tables IV. and V.)

Increasing the temperature (100° C. and upwards) the reduction of the amide occurs sufficiently rapidly and the exchange reaction appears. The activation energy for this exchange reaction is found to be 15 kg. cals. This is not the activation energy for the migration of hydrogen or deuterium which is much smaller namely 8 kg. cals.; it is more likely to be associated with the reaction

itself, whereas the back reaction, the dissociation, must have a smaller energy of activation not being the rate determining step. It is therefore most probable that the greatest part of this energy of activation is due to the exothermicity of the reaction  $\text{NH}_3 \rightarrow \text{NH}_2 + \text{H}$ .

The apparent energy of activation as calculated from the dependence of the reaction rate on temperature includes the heats of adsorption for the reactants. Owing to the strong adsorption of the ammonia we might assume that the adsorption layer is saturated with NH<sub>3</sub> over the whole temperature range and that therefore the heat of adsorption for NH<sub>3</sub> does not affect the true energy of activation. We do not know the exact heat of adsorption of D<sub>2</sub> but it will not be more than a few kg. cals. and therefore the true energy of activation will be somewhat larger than the apparent one. The concentration of deuterium will be rather low in the adsorption layer and this explains why the rate of exchange is approximately proportional to the square root of the deuterium pressure (Tables IV. and V.).

At still higher temperatures (over 300° C.) two new processes come into play, the decomposition of the surface nitride into molecular nitrogen and the migration of the nitride-N into catalyst the first reaction being responsible for the decomposition of ammonia, the second for the formation of iron nitride in bulk.

The author has great pleasure in expressing his indebtedness to Professor E. K. Rideal, F.R.S., for many discussions and his constant interest in this work. His thanks are also due to the Imperial Chemical Industries Ltd., for a grant.

### Summary.

The exchange of hydrogen atoms between  $D_2$  and  $NH_3$  has been investigated on an iron catalyst at pressures of 30 to 400 mm. Hg and temperatures of  $160^\circ$  to  $230^\circ$  C.

The rate of the exchange reaction is independent of the ammonia pressure and increases with increasing  $D_2$  pressure.

The apparent heat of activation is 15 kg cal.

The *ortho-para*-conversion of hydrogen and deuterium and the interaction  $H_2 + D_2 = 2HD$  proceed much more quickly than the exchange reaction the activation for the conversion reactions being 8-9 kg cal. The *ortho-para*-conversion of hydrogen is inhibited by the presence of  $NH_3$ .

It is suggested that the exchange reaction proceeds by the mechanism (all reactions occurring in the adsorption layer)

the step (c) being the slowest reaction and thus determining the rate. The reactions (a) and (d) are those involved in the conversion reactions. It is shown that this mechanism is in agreement with the experimental results.

## THE MECHANISM OF ELECTROLYTIC PROCESSES. PART I. THE ANODIC OXIDATION OF SOME METALS OF THE PLATINUM GROUP.

BY J. A. V. BUTLER AND G. DREVER.

*Received 11th October, 1935.*

In previous papers<sup>1</sup> the anodic polarisation of platinum electrodes has been studied in some detail and the observations made were interpreted as showing that, prior to the establishment of the oxygen over-voltage, an adsorbed layer of oxygen is formed on the surface of the electrode. No evidence was obtained of the formation of a definite platinum oxide similar to that which can easily be demonstrated at gold electrodes, which has been postulated by some investigators.<sup>2</sup> We have now examined the behaviour of the metals palladium, iridium and rhodium, and find that a similar phenomenon occurs in the initial stages of their anodic polarisation. Under certain circumstances the

<sup>1</sup> Butler and Armstrong, *Proc. Roy. Soc.*, 1932, 137A, 604; Armstrong, Himsworth and Butler, *ibid.*, 1933, 143A, 89.

<sup>2</sup> Cf. Bowden, *ibid.*, 1929, 125A, 446; Hoar, *ibid.*, 1933, 142A, 628.

formation of a distinguishable "oxide" can be demonstrated at palladium and rhodium electrodes, but in the case of iridium, like platinum, no such formation has been observed.

### Experimental.

The experimental cell (Fig. 1) consisted of two cylindrical vessels connected through a tap D. This was normally kept closed and prevented products at the cathode C reaching the anode B. Connection with the

FIG. 1.—Electrolytic vessel.

standard electrode (E) was made with a fine tube, the end of which was almost in contact with the anode, so as to avoid the inclusion of the fall of potential in the electrolyte in the measured potential. The tubes F and G served to introduce oxygen-free nitrogen by means of which air was removed from the vessel.

The potential difference between the standard electrode and the anode was observed by means of a potentiometer in conjunction with a Lindemann electrometer, which enables rapid readings of variable potentials to be made. The electrode potentials have been reduced to the standard hydrogen scale. The

electrodes were made of foil supplied by Messrs. Johnson, Mathey & Co., and had a total apparent area of 1 cm.<sup>2</sup>. Unless otherwise stated the experiments were carried out in an atmosphere of purified nitrogen.

### The Adsorbed Oxygen Layer of Palladium, Rhodium and Iridium.

It has been found that if a platinum electrode is anodically polarised from a sufficiently negative value a comparatively slow linear change of potential occurs before the oxygen overvoltage is reached. The quantity of electricity passed in this process is of the same order as that required for the deposition of a single layer of oxygen atoms on the surface of the electrode, and it has been suggested that such an adsorbed layer is formed. This adsorbed layer is removed by cathodic polarisation to near the reversible hydrogen potential and the process can be repeated. But, if the anodic polarisation is begun at a more positive potential, such that the adsorbed layer previously formed has not been destroyed, the potential falls much more rapidly and the quantity of electricity then required (per volt) to change the potential is taken as a measure of the double layer capacity of the electrode in the absence of a depolarisation process.

Similar phenomena were observed with all three metals, and some

typical anodic curves taken after cathodic polarisation to near the reversible hydrogen potential, in dilute sulphuric acid, are shown in Fig. 2. Table I.

FIG. 2.—Anodic polarisation of (A) palladium, (B) Rhodium, (C) Iridium electrodes in dilute sulphuric acid (numbers represent currents in microamperes). A\* is a "capacity" curve of palladium.

gives the quantities of current passed in the linear portions of these curves and the double layer capacities,  $B$ , which establish the real relative areas

It can be seen that the linear portion of the curve is in each case of the same order as that which is required for the deposition of a single layer of oxygen. In the case of platinum and rhodium it is appreciably smaller numerically, which may be due either to the difficulty of making an exact estimate of  $B$ , or to the intervention of the liberation of oxygen while the "adsorbed layer" is still incomplete.

FIG. 3.—Effect of interval between the removal of the adsorbed oxygen and the anodic polarisation, with palladium electrode in presence of oxygen. Curve 1, anodic immediately after cathodic; curve 2, interval of two minutes; —x— interval of one hour; —○— interval of sixteen hours.

In order to see whether the adsorbed oxygen layer is formed at the surface of the metal on standing in contact with oxygen some experiments were carried out in which different intervals of time were allowed between the cathodic polarisation and the subsequent anodic, in solutions containing oxygen. Some curves obtained with palladium are shown in Fig. 3. After an interval the potential falls to a more positive value before the linear change, which has the same slope as before, occurs. The first part of the adsorption curve is thus missing, so that some adsorption of oxygen has taken place during the interval. This, however, does not proceed to the extent of the formation of a complete adsorbed layer even after a long interval.

### The Formation of "Oxides" on the Electrodes.

After anodic polarisation the electrodes were cathodically polarised with a small current and the change of potential with the time was observed to see if any characteristic break occurs, such as has been observed with gold, representing the reduction of an oxide. With small anodic currents

FIG. 4.—Cathodic curves of a palladium electrode after anodic polarisation in dilute sulphuric acid (Table II.). Inset, effect of interval on the length of the cathodic break (full line, unstirred ; dashed line, stirred during interval).

the behaviour of all three metals was very similar to platinum, since only one depolarisation stage was observed in the cathodic curve which was clearly due to the reduction of the free oxygen liberated in the anodic process. It was observed that the decay at open circuit of the oxygen over-voltage was abnormally slow<sup>2</sup> with palladium electrodes, and this suggested the possible formation of traces of an oxide. It was then found that if the palladium electrodes were anodically polarised with much larger currents (of the order of 1 milli-ampere), a new depolarisation process occurred in the cathodic curve. Some examples of the cathodic curves obtained in dilute sulphuric acid are shown in Fig. 4. This process, which is clearly distinguished from the reduction of oxygen, since the latter occurs at a more negative potential, is interpreted as being due to the reduction of a superficial "oxide." The amount of oxide formed, as measured by the quantity of current required to take the potential to  $E_H = +0.72$  volts, increases with the amount of anodic polarisation, but even after considerable anodic treatment it remains very small and in this case is cer-

<sup>2</sup> Cf. Armstrong and Butler, *Trans. Faraday Soc.*, 1933, **29**, 1261.

tainly less than a single molecular layer. A representative series of experiments is given in Table II.

TABLE II.—FORMATION OF "OXIDE" AT PALLADIUM ELECTRODES IN DILUTE SULPHURIC ACID.

Anodic Current,  $700 \times 10^{-8}$  amps.; Cathodic Current,  $5 \times 10^{-8}$  amps.

Experiment.	Anodic Coulombs.	Cathodic Coulombs to + 0.72.	Experiment.	Anodic Coulombs.	Cathodic Coulombs to + 0.72.
1	$42 \times 10^{-3}$	$7.0 \times 10^{-4}$	5	$209 \times 10^{-3}$	$8.3 \times 10^{-4}$
2	83	7.5	6	418	8.8
3	125	8.0	7	1255	10.0
4	167	8.2	—	—	—

If an interval is allowed between the anodic and the subsequent cathodic treatment, the length of the cathodic break is decreased and after about twenty minutes it has practically disappeared (Fig. 4, inset). Stirring the solution during the interval somewhat increases the rate of disappearance. The most probable interpretation of this behaviour is that the "oxide" has the properties of a peroxide, which decomposes spontaneously after the stoppage of the current. On this view its half-life period under these conditions is rather less than ten minutes.

The "peroxide" is, however, much more stable in dilute alkali, the decrease in the length of the reduction process being only about 8 per cent. in an interval of five minutes. Comparative experiments are thus more easily made in this solution. In experiments designed to ascertain the efficiency of the peroxide formation it was found that the amount formed was dependent on the previous history of the electrode. The oxidation occurs more readily at an electrode which has previously been oxidised and reduced than at an untreated electrode. This is illustrated by Table III., which shows a series of consecutive experiments in which the electrode was treated anodically first for increasing and then for decreasing times. Between each experiment the adsorbed layer was completely removed by cathodic polarisation.

TABLE III.—CONSECUTIVE EXPERIMENTS WITH A PALLADIUM ELECTRODE IN  $N/5$  NaOH.

Anodic Current,  $540 \times 10^{-8}$  amps.

Experiment.	Anodic Coulombs.	Cathodic Coulombs to + 0.08.	Experiment.	Anodic Coulombs.	Cathodic Coulombs to + 0.08.
1	$11 \times 10^{-3}$	$5.3 \times 10^{-4}$	9	$2,600 \times 10^{-3}$	$10.5 \times 10^{-4}$
2	22	5.6	10	4,900	16.7
3	32	5.9	11	11,000	33.7
4	65	6.2	12	20,500	43.5
5	130	6.7	13	320	18.6

7	550	7.6	15	30	13.1
8	1300	8.7	—	—	—

It can be seen that after long anodic polarisations a comparatively small amount of anodic treatment causes a much greater amount of oxidation than in the original state of the electrode. Since the adsorbed layer has been removed between successive experiments, the effect must be due to some change in the nature of the underlying metal which is produced

by the oxidation, but persists after the reduction of the oxide. The effect, however, disappears when the electrode is left untreated for a few days, for the electrode reverts to its original condition.

With larger currents of the order of 1 milliampere an appreciably greater amount of oxidation took place and a visible black film appeared on the anode.

TABLE IV.—OXIDATION OF PALLADIUM IN  $N/5$  NaOH WITH  $8.5 \times 10^{-3}$  AMPS.

(3)	5100	35	(6)	(8.4) *	48

\* With  $i = 28 \times 10^{-4}$ .

It was again found that when the oxidation had once taken place, the oxide was reformed much more easily than initially. The final experiment shows that the oxidation can now be effected with small currents and that the efficiency of oxidation in the early stages is high. Even in the reduced state the electrode had lost its brightness, but after a few days' rest the brightness returned and the electrode reverted to its original condition.

Similar effects were observed with rhodium electrodes. No appreciable oxidation was at first observed with small anodic currents, but with large currents an additional depolarisation process similar to that of palladium appeared in the cathodic curve. The peroxide is not so stable as that of palladium for in dilute alkali ( $N/5$ ) its amount decreased by about 15 per cent. in six minutes.

Like palladium, rhodium is rendered more susceptible to attack by previous anodic treatment. It was found that after oxidation with a large anodic current, even very small anodic currents, which were previously ineffective, were able to produce oxidation. It was therefore possible at such electrodes to observe the growth of the peroxide from the earliest stages of the anodic process. A current of  $10.4 \times 10^{-4}$  amps. was passed

tial to the given value,  $Q_2$  the amount required at an untreated electrode in the normal formation of the adsorbed oxygen layer. The difference  $Q_1 - Q_2$  is the amount which has presumably been employed in the formation of

anodically, taking the potential in successive experiments to increasingly positive values. After each such anodic polarisation the current was reversed and the amount of "oxide" measured by the quantity of current required to take the potential to -0.02 volts. The adsorbed oxygen layer was destroyed by further cathodic polarisation before the next anodic treatment. The results are shown in Table V.  $Q_1$  is the total anodic polarisation required to take the poten-

the peroxide.  $Q_p$  is the amount of cathodic polarisation required to reduce the peroxide.

The figures in column (2) are based on the assumption that the amount of current required to produce the adsorbed layer is the same as in the original state of the electrode. That this is not far from true is shown by the approximate agreement of columns (3) and (4). Thus it is evident that at a previously oxidised electrode, the peroxide is formed simultaneously with the deposition of the adsorbed oxygen and at about the same rate. The formation of peroxide continues at a slow rate, however, after the evolution of oxygen has begun.

When the electrode is in this state, it is not possible to obtain either the normal anodic "capacity" curve, or the curve normally representing the formation of the adsorbed layer. Fig. 5 shows curves representing the anodic polarisation from two different potentials. Before curve A the electrode has been taken to near the reversible hydrogen potential, so as to destroy the adsorbed layer of oxygen. The anodic curve is flatter than the normal, the quantity of current passed being that required to deposit the adsorbed layer, with the concomitant "peroxidic" oxygen (*cf.* Table V.).

Before curve B the electrode has been polarised cathodically sufficiently to reduce the "peroxidic" oxygen but not to destroy the adsorbed layer. The quantity of current passed is thus that required to replace the peroxidic oxygen. The differences between the quantities of current required to reach

FIG. 5.—Anodic polarisation of a rhodium electrode in 0.2N NaOH.

various potentials in curves A and B, which are shown by curve C, should therefore represent the current used in forming the adsorbed layer. Since this corresponds fairly closely with that of a normal electrode, it appears on this ground also that the electrode area has not been much increased by the previous anodic treatment.

Similar experiments were made with iridium electrodes in dilute acid and alkaline solutions, but no evidence of peroxide formation was obtained. In the case of platinum no signs of this behaviour had been observed in the experiments previously recorded, and new experiments were made with comparatively large currents, but no oxidation was observed. However, it has been noticed,<sup>4</sup> that the rate of decay of the overvoltage at open circuit is slower than the theoretical rate for the first 100 seconds after stopping the current. It was suggested that this was "due to a slight electromotive activity by the oxygen formed in the electrolysis, which remains for a time (about one minute) and then disappears." By analogy with the other metals this behaviour might reasonably be attributed to the formation of a small amount of peroxidic oxygen which decomposes in dilute sulphuric acid in less than 100 seconds.

<sup>4</sup> Armstrong and Butler, *loc. cit.*<sup>1</sup>

### Discussion.

The formation of peroxidic layers has been demonstrated in the case of two of the four metals of the platinum group investigated. In the first place it is necessary, in view of the small quantities of oxide formed, to consider whether the effects might not be produced by the deposition of peroxides from traces of metallic impurities in the solution. If this were the case we should expect the electrodes of different metals to behave similarly and the phenomenon observed would be characteristic of the solutions rather than of the metals. To obtain conclusive evidence on this point a platinum and a palladium electrode were placed in the same solution and treated similarly. Peroxidation of the kind described occurred at palladium, but none was to be observed on the platinum.

The oxide is formed extremely slowly at a new electrode. In the case of rhodium the maximum amount observed is of the same order as a single molecular layer, while with palladium after very large amounts of anodic polarisation a layer of oxide several molecules deep is formed. When the oxide has once been formed, and reduced, it is very readily reformed.

Since the rate of oxidation is so small that it takes a considerable time to form even a single molecular layer of oxide, some parts of the surface must be more readily oxidised than others, and it must be supposed that the oxidation begins at exposed atoms or edges and spreads over the surface. This may be because the attachment of an exposed atom to the surface is so weakened by the attached oxygen that it is pulled out from the surface giving rise to a definite molecule of oxide, while the underlying metal atom now takes up an adsorbed oxygen, viz. :—

But since the oxidation occurs more rapidly with a greater current it is probable that the oxygen liberated is concerned in the formation of the oxide. This could happen if an exposed metal atom could take up a second oxygen atom as in (a), which will be "peroxidic" in character since it is more loosely held :—

The exposed atom is then pulled away from the surface, giving rise to a definite molecule of oxide as in (b), while an oxygen atom can then be adsorbed on the underlying metal atom. The stage (a) has not been directly observed, but indications of it are to be found in the slight electromotive activity which is observable at platinum after the stoppage of the current. This may be due to a slight peroxidation as in (a), without any distinguishable oxide formation.

The attack of an insoluble metal by oxygen at the anode thus takes place in the following stages. The formation of an adsorbed layer of oxygen is probably followed by the addition of peroxidic oxygen at exposed parts of the surface. With the more inert metals, platinum and iridium, the process stops here, but if the forces between the metal atoms are not so great the attachment of the "peroxidised" atoms to the surface may be so weakened that distinct molecules of the oxide are formed, and the neighbouring atoms are then left open to attack. This occurs very slowly with palladium and rhodium, more rapidly with gold and as will be shown in a further communication, very readily with the more easily oxidised metals, lead and nickel. When the surface oxide is reduced the atoms are probably redeposited in a chaotic condition and are readily reoxidised, but if the electrode is left standing for a few days a process akin to crystallisation takes place and the electrode reverts to its original inactive state.

It is unlikely that this phenomenon has any direct bearing on the oxygen overvoltage, for the rate of decomposition of the peroxide is not sufficient to make it a factor in the liberation of oxygen at the electrode, but it may have a secondary influence owing to the changes in the nature of the surface which are brought about. It has in fact been observed that in the continuous liberation of oxygen at a constant rate at these metals, the overvoltage continues to increase for some hours.

We thank Messrs. Imperial Chemical Industries and the Earl of Moray Endowment for grants for apparatus and materials respectively.

### Summary.

1. When electrodes of palladium rhodium and iridium are anodically polarised in acid and alkaline solutions, an adsorbed layer of oxygen is formed prior to the establishment of the oxygen overvoltage, similar to that previously demonstrated in the case of platinum.

2. With palladium and rhodium a second stage in the oxidation has been observed, *viz.*, the slow formation of oxides of a peroxidic character, which are reduced cathodically at a more positive potential than the adsorbed oxygen. The conditions of formation of these oxides have been investigated, and a mechanism of the oxidation suggested.

## THE MECHANISM OF ELECTROLYTIC PROCESSES. PART II. THE ELECTROLYTIC OXIDATION OF SODIUM SULPHITE.

BY J. A. V. BUTLER AND W. M. LESLIE.

*Received 11th October, 1935.*

In recent years considerable additions have been made to our knowledge of the conditions under which oxygen is liberated in electrolysis at the anode, and a stage has been reached at which it is appropriate to reconsider the mechanism of electrolytic oxidations. Bowden<sup>1</sup>

<sup>1</sup> Bowden, *Proc. Roy. Soc.*, 1929, 126A, 107.

showed that Tafel's relation  $i = ke^{-aV}$ , where  $a = 2F/RT$ , is obeyed in the liberation of oxygen at the anode, and if Gurney's quantum mechanical interpretation<sup>3</sup> of this relation is correct this implies that the discharge takes place by the transfer of electrons from (hydrated) hydroxyl ions near the electrode. It has, however, been shown<sup>3</sup> that before the voltage necessary for the liberation of oxygen is reached, a layer of adsorbed oxygen atoms is formed on the electrode surface of platinum and other noble metals. In the case of palladium and rhodium<sup>4</sup> a small amount of peroxidic oxide also is slowly deposited during the oxygen evolution. At the more easily oxidisable metals such as lead and nickel, oxides of a peroxidic nature are formed by anodic polarisation in appreciable quantities.

The possible processes by which an electrolytic oxidation may be effected may thus be listed as follows:—

A. A primary electrochemical oxidation by the direct transfer of electrons to the electrode from the substance in solution or adsorbed on the electrode surface.

B. A secondary oxidation brought about by a primary product of the electrolysis, such as:

(1) Atomic oxygen liberated by the primary discharge of hydroxyl ions;

(2) Adsorbed oxygen;

(3) Any other primary product of the electrolysis, e.g., superficial peroxides.

It is possible to distinguish between these processes to some extent by observing the electrode potentials at which the oxidation takes place. If the primary process is the liberation of free oxygen which effects the oxidation by a secondary reaction with the depolariser, the potential should be that at which oxygen is normally produced under the given circumstances. The adsorption of the depolariser on the electrode may cause displacement of the potential in this case, but since this reduces the effective surface of the electrode the displacement will be in the positive direction. Therefore if the oxidation occurs at a more negative potential than that at which oxygen is produced under the same conditions in the absence of the depolariser, the mechanism B1 is ruled out.

It will also be possible sometimes to distinguish other cases, e.g., when the electrolytic oxidation takes place at a more negative potential than that at which the deposition of adsorbed oxygen begins a primary electrochemical process (A) is indicated. If the oxidation takes place in the same region as that in which adsorbed oxygen is formed, a distinction between processes A and B2 will sometimes be possible by observing the effect of varying the  $p_H$  of the solution.

In order to find a system suitable for quantitative study preliminary experiments were made with solutions of aniline, methyl alcohol and formaldehyde. The first gave rise to insoluble films on the electrode, the second appeared to be oxidised in two distinct stages, while formaldehyde easily gave rise to insoluble polymerisation products. Finally, the oxidation of sodium sulphite was chosen as a suitable reaction.

<sup>3</sup> Gurney, *Roy. Proc. Soc.*, 1931, 134A, 137.

<sup>3</sup> Butler, Armstrong and Himsworth, *ibid.*, 1933, 143A, 89.

<sup>4</sup> Butler and Drever, this vol., p. 427.

This oxidation has already been extensively studied, the main products being sulphate and dithionate. Foerster and Friesner<sup>5</sup> and Friesner<sup>6</sup> found that the yield of dithionate was influenced by the nature and the previous treatment of the electrode and for this reason the latter rejected the simple electrochemical mechanism ( $2\text{SO}_3^- = \text{S}_2\text{O}_6^- + 2e$ ) and suggested that the oxidation was effected by oxygen, *viz.* :—

Essin<sup>7</sup> extended this view and suggested that no dithionate could be formed until a certain pressure of oxygen was reached, but Glasstone and Hickling<sup>8</sup> have shown that this view is untenable since dithionate is formed as readily at less as at more positive potentials. The latter have re-examined the conditions and products of the oxidation and, in line with their general theory of electrolytic oxidation,<sup>9</sup> suggest that the primary product which effects the oxidation is hydrogen peroxide. It is supposed that dithionate is formed by the action of hydrogen peroxide alone, while sulphate is produced both by hydrogen peroxide and its decomposition product, oxygen. Thus any circumstances which favour the decomposition of hydrogen peroxide should increase the yield of sulphate. It was found that the addition of substances ( $\text{Mn}^{++}$ ,  $\text{Co}^{++}$ ,  $\text{Fe}^{++}$ , powdered Ag) which are known to be catalysts for the decomposition of hydrogen peroxide decreases the yield of dithionate. Walker and Weiss<sup>10</sup> have, however, pointed out that under the conditions of Glasstone and Hickling's experiments on the effect of catalysts on the Kolbe synthesis, oxidic films are frequently deposited on the electrode and the change in the nature of the electrode surface is quite capable of producing the variation of the oxidation products.

### Experimental.

**Procedure.** The object of these experiments was to see whether the possible mechanisms of the oxidation could be distinguished by a study of the current-potential and time-potential curves. The classical method of determining current-potential curves, in which a definite voltage is applied to the cell and the final value of the current passing is observed, often fails to give information as to the initial stages of the electrolysis. In this work constant currents were employed and observations made of the potential of the electrode a definite time after starting the current. In many cases supplementary information was also obtained by observations of the potential with the time. The experiments were made on un-stirred solutions, since this has been found to be a convenient means of observing consecutive processes.

Sodium sulphite solutions in ordinary distilled water are fairly rapidly oxidised, owing probably to the catalytic influence of traces of copper. The water employed was redistilled in a Pyrex apparatus from barium hydroxide and potassium permanganate, and gave reasonably stable solutions, with which reproducible time-potential curves could be obtained.

The buffer solutions of  $p_H$  6-8 were of  $M/20$   $\text{KH}_2\text{PO}_4$ , with the appropriate additions of NaOH, while those of  $p_H$  9-10 contained  $M/20$   $\text{H}_3\text{BO}_3$ .

$M/20$  KCl with appropriate amounts of alkali. It was found by the use of indicators that the addition of  $M/100$   $\text{Na}_2\text{SO}_3$  did not cause a significant change of the  $p_{\text{H}}$  of these solutions.

The electrodes were of platinum foil of 2 cm.<sup>2</sup> apparent area. When observing the variation of the potential with time, the electrode was prior to each experiment cathodically polarised to near the reversible hydrogen potential and the solution was then stirred by passing a stream of nitrogen for five minutes. When this procedure was carried out exactly reproducible curves were obtained. The current-potential curves, which show the potential reached a definite time after starting the current (fifty seconds) were obtained from the time-potential curves when the change of potential with time was appreciable. When the latter was small, the potential was observed at the stated interval. The apparatus was similar to that described in Part I.

### The Current-Potential Curves of $N/100$ $\text{Na}_2\text{SO}_3$ in Solutions of Various $p_{\text{H}}$ .

These curves, which are shown in Fig. 1, give a general picture of the conditions under which the oxidation takes place. It can be seen that

FIG. 1.—Current-potential curves for  $N/100$   $\text{Na}_2\text{SO}_3$  in buffer solutions of various  $p_{\text{H}}$ .

FIG. 2.—Time-potential curves for  $N/100$   $\text{Na}_2\text{SO}_3$  in buffer  $p_{\text{H}}$  7. The numbers on the curves refer to the current in amps  $\times 10^{-4}$ .

with small currents the electrolysis begins between  $E_{\text{H}} = +0.65$  and  $+0.75$ , but as the current is increased a transition occurs and the potential falls to near the oxygen discharge potentials of the buffer solution. While the potential of the initial stage is not much affected by the  $p_{\text{H}}$  of the solution (it moves slightly towards the positive as the  $p_{\text{H}}$  increases), that of the final stage is considerably displaced in the negative direction by increase of  $p_{\text{H}}$ . The fall of the potential which occurs in the transition is thus small in alkaline solution and becomes greater as the acidity increases. The current at which the transition to the lower potential stage takes place increases as the  $p_{\text{H}}$  is decreased.

It has been found<sup>11</sup> that the transition current, when determined in this way, is approximately proportional to the concentration of the depolariser. The magnitude of the change observed is, however, comparatively small over a wide range of  $p_{\text{H}}$ , and it cannot be concluded that

<sup>11</sup> Butler and Armstrong, *Proc. Roy. Soc.*, 1932, 137A, 604.

the change is due to the relative concentrations of the  $\text{HSO}_3^-$  ion, which vary very much more widely in these solutions. Indeed we may conclude from the comparative independence of the potential of the initial stage, together with the small variation of the transition current that the process is not affected by the proportions of  $\text{HSO}_3^-$  and  $\text{SO}_3^{2-}$  present in the solution.

### The Time-Potential Curves.

In order to find the cause of the transition observed above, the variation of the potential with time was observed in various solutions with currents in the neighbourhood of the transition current. A typical series obtained with  $N/100$   $\text{Na}_2\text{SO}_3$  in a buffer solution of  $p_H$  7 is shown in Fig. 2. Similar curves were obtained with other concentrations of sulphite. Defining the transition time  $t$  as the time in which the potential reaches  $+1.2$  volts, it is found that for each solution the relation

FIG. 3.—Effect of concentration of  $\text{Na}_2\text{SO}_3$  (in buffer of  $p_H$  7) on the length of the anodic break ( $t$ ) to  $E = 1.2$  volts.

it is found that for each solution the relation

$$it \sim i_0 t + \alpha$$

holds, where  $i$  is the current, and  $i_0$  and  $\alpha$  are constants. The graphs of  $it$  against  $t$ , which demonstrate this relation are shown in Fig. 3. The following table shows the values of  $i_0$  and  $\alpha$  for the various concentrations, and it can be seen that, except at the highest concentration, these constants are approximately proportional to the concentration. This relation has been obtained under similar conditions in a number of other electrochemical reactions<sup>12</sup> and has been interpreted in these cases as a consequence of the depletion of the depolariser near the electrode.  $i_0$  represents the limiting current below which no transition occurs. When the current is smaller than this value, the depolariser can reach the surface by diffusion from the solution at a rate equal to or greater than that at which it is being removed; but when a greater current is employed the rate of removal of the depolariser by the electrochemical process is

CONSTANTS OF EQUATION  $it \sim i_0 t + \alpha$  IN VARIOUS CONCENTRATIONS OF SODIUM SULPHITE.

C.	$i_0$ (Amps. $\times 10^{-3}$ ).	$\alpha$ (Coulombs $\times 10^{-2}$ ).
0.0025	65	0.4
0.005	125	0.8
0.01	290	1.5
0.02	570	3.3
0.04	1850	8.3

greater than the rate of diffusion and ultimately the supply of depolariser near the surface is exhausted, and the potential falls to a lower value at which an alternative process can take place. We may therefore conclude that the transition observed in this reaction is due to the same effect.

<sup>12</sup> *Loc. cit.*, (11) and (3).

### The Nature of the Oxidation Process.

We have now to consider the nature of the process which occurs in the primary stage of the electrolysis. It is known that adsorbed oxygen is formed over a range of potentials more negative than that at which oxygen is liberated. This range has not been clearly defined, and experiments were made to define the region in the buffer solutions employed. The curves obtained in a buffer of  $p_H$  7 are shown in Fig. 4a. The group A, of the anodic polarisation in the buffer solution containing no sulphite, shows the linear stage XY which indicates the deposition of adsorbed oxygen. The group B, of the same solution containing  $N/100$   $Na_2SO_3$ , shows clearly that the electrolysis begins at a more negative potential than that at which the formation of adsorbed oxygen takes place. The electrolytic process taking place in this solution cannot be due to prior formation of adsorbed oxygen. On the other hand, in more alkaline solutions, the oxygen forming

FIG. 4.—Time-potential curves of solutions (A) without and (B) with  $N/100$   $Na_2SO_3$ . The currents with which the curves were obtained, taken in order downwards in amps.  $\times 10^{-7}$  are: (a) Group A, 380, 470, 630, 830; Group B, 380, 470, 830, 2030; (b) Groups A and B, 420, 700.

processes move towards more negative potentials, while the potential at which oxidation takes place is comparatively unaffected. Thus it is found (Fig. 4b) that in alkali the oxidation occurs within the region in which adsorbed oxygen might be formed. In alkaline solutions it is therefore a possibility that the oxidation is effected by adsorbed oxygen, but it is very unlikely that the fundamental mechanism varies with the  $p_H$ .

### Effect of Catalytic Substances.

Glasstone and Hickling<sup>13</sup> found that the addition of salts of manganese, cobalt, iron, etc., caused a profound change in the course of the electrolytic oxidation. The yield of dithionate (except with cobalt additions) was markedly reduced and in the case of manganese the initial potential stage was nearly suppressed. They interpreted these changes in terms of their hydrogen peroxide theory, but Walker and Weiss have shown that in another oxidation process (Kolbe reaction) under the conditions of

<sup>13</sup> *Loc. cit.*, (8), also *J. Chem. Soc.*, 1934, 136, 1878.

Glasstone's experiments visible films of "oxides" are frequently formed on the anode.

We examined the effect of small amounts of various salts on the time-potential curves under the conditions previously described. A phosphate buffer of  $p_H$  7 was employed to which only small concentrations of the salt could be added without precipitation. Cobaltous, chromic and ferric salts at  $M/5000$  caused small displacements of the initial stage in the positive direction, without having much effect on the transition time. The effect of manganese sulphate is shown in Fig. 5. It is observable even at  $M/250,000$ , and the initial potential stage is almost entirely suppressed at  $M/2500$ . In these more concentrated solutions a visible oxide film was formed on continued anodic polarisation and a study was therefore made of the conditions of its formation.

### The Anodic Formation of $MnO_2$ Films.

In these experiments the solutions in the electrolysing cell were rigorously freed from oxygen by bubbling purified nitrogen for a considerable time. The nitrogen was purified by passing over red hot copper, followed by alkaline pyrogallol. The freedom of the solution from oxygen was shown by the absence of an oxygen break in the cathodic curve even when the solution was vigorously stirred.

It was found that manganese salts were precipitated in the phosphate buffers and in alkaline solutions at concentrations above  $M/2500$ , so that in order to use a greater concentration dilute sulphuric acid was employed as electrolyte in these experiments.

The conditions under which the film is formed are illustrated in Fig. 6, which shows the behaviour of  $M/100$   $MnSO_4$  in  $M/100$   $H_2SO_4$ . The anodic curve *abc* shows first the linear part *ab* along which the deposition of adsorbed oxygen occurs. In sulphuric acid alone this would continue to about +1.5 volts, but in the presence of the manganese the curve becomes horizontal (after a slight kink) at about +1.3. The cathodic curves were obtained by reversing the current after various periods of anodic polarisation. After seventy seconds anodic (which brings the potential to the point *b*) the cathodic curve shows a well-marked break *gh*, which is nearly equal in length to the linear stage *ab* and represents the removal of the adsorbed oxygen. After longer anodic polarisations it remains constant, but a new cathodic stage *df* appears, which is nearly equal to the length of the anodic treatment after the point *b*. This process is evidently the removal of the oxide film formed along *bc*. The oxide is thus formed and reduced at potentials only slightly removed from each other and the process of its formation and reduction is evidently reversible. The potential at which these processes occur is  $E_H = +1.3$ , which is in agreement with the recorded  $MnO_2/Mn^{++}$  potential<sup>14</sup> for a solution of the same acidity, so that it can be concluded that the oxide deposited is  $MnO_2$ .

FIG. 5.—Effect of  $MnSO_4$  on the time-potential curves of  $N/100$   $Na_2SO_3$  in  $p_H$  7;  $i = 380 \times 10^{-6}$  amp. (1) No Mn; (2)  $M/250,000$  Mn; (3)  $M/10,000$  Mn; (4)  $M/2500$  Mn.

<sup>14</sup> Tower, *Sitz. Akad. Wiss., Wien* 1900, 32, 566; quoted in *I.C.T.*, vol. VI.

In some experiments with a larger anodic current ( $125 \times 10^{-6}$  amps.), it was observed that signs of the film were just visible after the passage of  $6 \times 10^{-3}$  coulombs; it was a uniform pale yellow after  $9 \times 10^{-3}$  coulombs, pale brown after  $19 \times 10^{-3}$  coulombs and brown and opaque after  $25 \times 10^{-3}$  coulombs. The latter probably corresponds to a film of the order of 10 molecules deep. A similar series of colours appeared in the reverse order on removing the film cathodically.

The amount of cathodic treatment required to remove the film is usually slightly less than the quantity of electricity passed anodically in its formation. The difference is accounted for by the fact that the oxide dissolves spontaneously at a slow rate in  $M/100$  sulphuric acid. The rate of solution is appreciably more rapid in  $M/10$  and more concentrated solutions.

Taking this into account the oxide is deposited with 100 per cent. efficiency with small currents from  $M/100$   $\text{MnSO}_4$ , but the efficiency of its formation becomes less when the concentration of manganese is reduced. Thus in  $M/10,000$   $\text{MnSO}_4$ , the anodic potential does not remain constant

FIG. 6.—Formation and destruction of  $\text{MnO}_2$  films;  $i = 25 \times 10^{-6}$  amp. Numbers on cathodic curves refer to time of previous anodic.

after the point *a*, but continues to fall slowly until the oxygen discharge potential is reached, and after  $17 \times 10^{-3}$  coulombs had been passed anodically the amount of oxide corresponded only to  $3.5 \times 10^{-3}$  coulombs.

The potential of the  $\text{Mn}^{++}/\text{MnO}_2$  electrode is determined by the reaction  $\text{Mn}^{++} + 2\text{H}_2\text{O} = \text{MnO}_2 + 4\text{H}^+ + 2e$ , i.e.,  $E = E^\circ + 2RT/F \log (\text{H}^+)$ , and thus for a constant concentration of  $\text{Mn}^{++}$  becomes more negative by 0.12 volts for each unit increase of  $p_{\text{H}}$ . The effect of the  $p_{\text{H}}$  on the deposition of  $\text{MnO}_2$  is thus twice that on the discharge of oxygen and while in an acid solution the deposition of the oxide begins only when the adsorbed layer of oxygen is nearly completed, in solutions having a  $p_{\text{H}}$  greater than 7 the oxide is formed *before* the deposition of adsorbed oxygen. Thus in these solutions the deposition of the oxide takes place in the same region as that in which the primary oxidation of sulphite takes place, so that the suppression of the primary stage in the presence of manganese ions can be accounted for as due to the formation of a film of oxide, which may in the early stages of its formation at any rate be quite invisible. Presumably the primary oxidation process cannot take place at an electrode covered with  $\text{MnO}_2$ .

### Discussion.

It has been shown that in  $p_H$  7 solutions the primary electrolytic oxidation takes place at a more negative potential than that at which adsorbed oxygen is formed, and indeed in a region in which no electrochemical process can be detected in the buffer solution alone. It is difficult to avoid the conclusion, contrary to that of previous investigators, that in this solution the oxidation is a primary electrochemical process brought about by the direct transfer of electrons from sulphite ions to the electrode. In more alkaline solutions ( $p_H > 9$ ) the region in which adsorbed oxygen is formed overlaps the potential at which the oxidation takes place and reaction between adsorbed oxygen and the sulphite is clearly a possibility. Since, however, the oxidation potential is only slightly affected by changes of  $p_H$  it may be concluded that the primary oxidation process continues to take place even in the more alkaline solutions.

In these experiments the quantities of electricity passed are very small and it is not feasible to examine the products of the reaction. Glasstone and Hickling have shown, however, that dithionate and sulphate are the main products, the yield of the former being less than a half of the total oxidation. The simplest way in which these substances could be formed by a primary process is as follows: if a sulphite ion  $SO_3^-$  loses two electrons to the electrode, the uncharged  $SO_3$  molecule may combine either with another sulphite ion or with water, *viz.*,

Similar processes are possible with the  $HSO_3^-$  ion.

It might be expected on this view that the yield of dithionate would be increased by an increase of the sulphite concentration, since the chance of the first reaction would be greater. According to Glasstone and Hickling's observations this is not the case. This difficulty would, however, occur in almost any theory of the reaction, since the dithionate must be formed from two sulphite residues. A possible reason is that the reaction takes place entirely between adsorbed materials and if the surface is practically saturated over the range of concentrations studied this effect would not occur.

In solutions of  $p_H > 9$  another reaction is possible, *viz.*,  $SO_3^- + O = SO_4^{2-}$ , which will increase the proportion of sulphate formed. Since the amount of adsorbed oxygen formed at a given potential increases with increase of alkalinity, this reaction will also occur to a greater extent. This explains Glasstone and Hickling's observation that the yield of dithionate is a maximum in the region  $p_H$  7 to 9 and decreases as the solution becomes more alkaline. They also found that the yield decreased in more acid solutions and became very small at  $p_H$  1. While we have made no experiments in this region, it may be suggested as a possible explanation that undissociated  $H_2SO_3$  and  $SO_2$ , which are largely present in the more acid solutions, are unable to bring about the dithionate reaction.

Glasstone and Hickling also observed a transition from a higher to a lower potential during the course of the oxidation, under the conditions of their experiments, *viz.*, long continued electrolysis with a

rotating electrode. It is difficult to judge the significance of this. Transition phenomena due to the depletion of the depolariser also occur in stirred solutions, the effect of stirring being to decrease the thickness of the diffusion layer and so increase the transition time. However, many samples of distilled water contain slight traces of metallic impurity in amounts quite sufficient to form films of oxide a few molecules thick on the electrode, and a possible cause of the transition is the formation of such films in the course of a long continued electrolysis.\*

In conclusion, we may observe that Glasstone and Hickling's arguments in favour of their hydrogen peroxide theory of electrolytic oxidation are almost entirely indirect, since it has not been shown that  $H_2O_2$  is a product of the electrolysis under the conditions of the experiments. The more important indirect arguments on which they rely are (1) the transition of the potential has no significant effect on the yield of dithionate; (2) the yield of dithionate is a maximum at  $p_H$  8 and decreases both in more acid and in more alkaline solutions, (3) the addition of substances which are catalysts for the hydrogen peroxide decomposition decreases the yield of dithionate. The first appears to be not clearly shown by Glasstone and Hickling's own curve, while it has been shown that the effect of changes of  $p_H$  can be alternatively explained. Finally the effect of catalytic ions can be attributed to the formation on the electrodes of peroxidic oxides at which the primary oxidation cannot take place.

### Summary.

1. The conditions under which the electrolytic oxidation of sodium sulphite occurs in buffer solutions of various  $p_H$  has been examined.
2. It is shown that in  $p_H = 7$  the oxidation takes place at a more negative potential than that at which adsorbed oxygen is formed. Since no other primary process is observed in this region with the buffer solution alone, it is concluded that the oxidation takes place in this solution by the direct transfer of electrons from the sulphite ions to the electrode. In solutions of  $p_H = 9$  the oxidation occurs in the same region as that in which adsorbed oxygen is formed so that in these solutions oxidation by adsorbed oxygen is a possibility.
3. The effect of various added salts was studied and it was found that in the case of manganous salts, which are much the most effective, the suppression of the initial stage of the electrolysis was due to the formation of a film of manganese dioxide.
4. The results of this investigation are not in accordance with Glasstone and Hickling's hydrogen peroxide theory. An alternative mechanism has been suggested.

We acknowledge gratefully a grant made to W. M. L. by the Ritchie Bequest.

*King's Buildings,  
West Mains Road,  
Edinburgh.*

\* Glasstone and Hickling regard the changes of potential which occur as secondary effects produced by the accumulation of oxygen at the electrode and suggest that the oxidation processes themselves are not affected by the potential change since the curves showing the total oxidation and the amount of dithionate formed show "no marked discontinuity." It may be observed, however, their curves show that the efficiency of dithionate formation does in fact decrease as the electrolysis is continued and is much smaller at the end than at the beginning. The analytical accuracy is probably insufficient to show if a change of slope is associated with the potential transition.

# THIXOTROPY AND RHEOPEXY OF $V_2O_5$ -SOLS.

BY F. JULIUSBURGER AND A. PIRQUET.

*Received 7th November, 1935.*

## I.

In a previous paper<sup>1</sup> there was described and briefly discussed a phenomenon found in some thixotropic systems which contain particles of strongly anisometric shape, *e.g.*, plate- or rod-like particles. Thixotropic sols (of  $V_2O_5$ ) or suspensions (of gypsum) having a certain time of solidification, when left to themselves, could be solidified in a very much shorter time by moving the liquid in a gentle and regular way; for instance, by rolling the test tube containing the sample to and fro between the palms of the hands. This new effect was named "rheopexy."

It was there assumed that the cause of this solidification is the orientation of the particles brought about by the movement of the liquid. If this were true, one would expect that other means of orienting the particles, for instance a magnetic field or an electric current, would favour solidification in these thixotropic sols. Preliminary experiments in this direction have so far not been successful. This and other facts leave it an open question, whether orientation of the particles is really the cause of, or only a phenomenon accompanying the rheopectic behaviour.

The following paper deals mainly with another question: how is rheopexy related to ordinary thixotropy?

Practically all experiments were done with  $V_2O_5$  sol. It showed valuable properties in many respects, although its lack of stability under certain conditions was a distinct drawback.

The experiments were performed in test tubes with ground-in glass stoppers having an inner diameter of 9 mm. Whether a sample had solidified or not, was tested by reversing the test tube carefully. Only when the gel did not flow at all, was it considered to be solid. The time, from the moment the gel had been fluidified by shaking till it had solidified, is referred to as the time of solidification  $\theta$ . By spontaneous solidification is understood the transformation of a sol into a gel, when the sample is left to itself without being moved or disturbed. This is the ordinary thixotropic solidification. It must be distinguished from the rheopectic solidification caused by a suitable movement.

It has been found convenient to construct a special "machine" in order to produce in a better defined and reproducible way the to and fro movement of the test tube which has proved useful for solidifying rheopectic sols. The principle is very simple. A disc is rotated by a motor. By a suitable transmission this rotation is transformed into a movement to and fro of a pulley. The latter bears a cylinder containing the test tube with the sample.

The speed of the machine could be varied and the influence of this variation was studied in order to find the speed which would cause the

<sup>1</sup> Freundlich and Juliusburger, *Trans. Faraday Soc.*, 1935, 31, 920.

quickest solidification of any given sample. A speed of about 120 to 140 changes per minute was found to be the most favourable in the majority of experiments. If the speed was too small, the movement of the liquid was not sufficiently strong and a longer time was needed to cause solidification. This was also the case, if the tube was moving too fast, probably because too strong a movement destroys the structure already formed. When dealing with a very viscous sol, the best working conditions were at a higher speed. In the majority of cases, however, the properties of the various samples justified keeping the machine at the speed mentioned, without change.

Another kind of regular movement was also most suitable for causing rheopectic solidification: instead of rolling the test tube one can tap it gently and regularly on the table, holding it in a vertical position. It is advisable to cover the board with a sheet of filter paper. Obviously any vibration may cause rheopectic solidification. With the rheopectic suspension of gypsum in water, mentioned in the previous paper, a weak action of ultrasonic waves can cause rheopectic solidification. This experiment was not so successful so far with the much more sensitive  $V_2O_5$  sols.

## II.

In the paper mentioned the  $V_2O_5$  sol showing rheopepy was about ten years old. Hence it was of interest to compare the properties of this sol, as to thixotropy and rheopepy, with those of a freshly prepared  $V_2O_5$  sol.

In the following experiments frequent references will be made to sol A, B, and C.

**Sol A** was a  $V_2O_5$ -sol which had aged about ten years. The amount of  $V_2O_5$ , found by evaporating and melting for a very short time, was 0.16 per cent. The sol was reddish brown in reflected, clear red in transmitted light. When stirred and viewed in reflected light distinct streaks were seen abundantly.\*

**Sol B** was a freshly prepared  $V_2O_5$  sol which had aged for 3 weeks at the start, and for 7 weeks at the end of the experiments. As with sol A the method of preparation was that given by Biltz.<sup>†</sup> The sol was dialysed in cellophane bags, which proved very suitable for this purpose. Dialysis went on for 3 weeks, the water being changed frequently. The appearance and properties of the dialysed sol differed markedly from those of the undialysed sample. The former evidently contained extremely small particles. The colour was almost black in reflected light, and deep red in transmitted light. The sol contained 0.72  $V_2O_5$ . For the sake of comparison, however, the sol was in some experiments diluted to the same concentration (0.16 per cent.) as sol A. Streaks were visible, when the sol was stirred, but they were much less pronounced than with sol A.

**Sol C** was prepared from sol B in the following manner: samples of sol B, contained in sealed test tubes, were heated in a water bath for about 47 hours. Care was taken not to expose the whole test tube to heating, for the reason that, if this were done, a part of the sol was destroyed, a coagulated deposit of  $V_2O_5$  being formed at the boundary sol/water vapour/glass. But if the boundary sol/water vapour was cooled from outside, thus maintaining convection currents within the sol, a decomposition of the sol could easily be avoided. Heating has a very strong effect: sol C finally resembles sol A, as to colour and distinctness of streaks. An exposure to higher temperature evidently causes, in a much shorter time, practically the same changes as ageing at room temperature does in a considerably longer time. Sol C had the same concentration of  $V_2O_5$  (0.72 per cent.) as sol B from which it had been prepared.

\* Diesselhorst, Freundlich and Leonhardt, *Elster-Geitel-Festschrift*, 1915, p. 453.

† W. Biltz, *Ber.*, 1904, **37**, 1098.

The thixotropic and rheopectic behaviour of these three sols was compared with their appearance under the ultramicroscope. Thus the influence of particle size upon thixotropy and rheopecty was examined.

We never succeeded in producing rheopecty with any sample of sol B; the time of solidification  $\theta$  was the same, whether the sol, after being vigorously shaken, was left to itself or was rotated on the machine. In one experiment  $\theta$  was in both cases 25 minutes (the sol contained 0.35 per cent.  $V_2O_5$  and 39 m. Mol.  $H_2SO_4/2$ , the acid having been added at once).

Sol B, the freshly prepared sol, was undoubtedly strongly thixotropic, when a suitable amount of  $H_2SO_4$  had been added, although it is not rheopectic. Under the ultramicroscope it was found to be optically void; only a Tyndall cone could be seen, but no single particles. This may be attributed entirely to the small size of the particles. For the difference in the refractive indices of  $V_2O_5$  and the surrounding aqueous solution is great and quite sufficient to allow visibility. Nevertheless sol B shows a distinct optical anisotropy: streaks appear, when it is stirred; a sign that the particles are anisometric.

Sols A and C were both thixotropic and rheopectic. In sol A  $\theta$  was, for example, 3 hours for the thixotropic, 8 minutes for the rheopectic change (the sol contained 0.15 per cent.  $V_2O_5$  and 48 m. Mol.  $H_2SO_4/2$ ; the acid was added at once). In sol C  $\theta$  was 20 minutes for the thixotropic, 1 minute for the rheopectic change (the sol contained 0.23 per cent.  $V_2O_5$  and 42 m. Mol.  $H_2SO_4/2$ ; the acid was added in 11 equal portions).

Under the ultramicroscope both sol A and C were found to contain long, needle-shaped particles with a length up to about  $10\mu$  and more.<sup>4</sup> In sol A particle size seemed to vary only slightly, whereas sol C appeared to be somewhat heterodisperse. In the latter there also were seen a number of particles which were considerably thicker than the majority of particles in this sol and in sol A, resulting probably from the somewhat crude procedure of preparing sol C from B. So long as no electrolyte was added, the needles showed Brownian movement. Most of them were so thin that they disappeared, when their long axis turned into a position parallel to the incident beam of light; they were obviously amicronic as to their two other dimensions.

When electrolyte was added in such an amount that it did not cause macroscopically visible coagulation, the Brownian movement gradually diminished until it ceased completely. The needles then seemed to form a kind of irregular structure. These ultramicroscopic experiments were

TABLE I.—SOL C.

The sol contained 0.23 per cent.  $V_2O_5$  and 42 m. Mol.  $H_2SO_4/2$ . The acid was added in 11 equal portions.

t.	$\theta$ .

42 days	more than 1 hour	10 mins.

$V_2O_5$  sols containing  $H_2SO_4$  are very unstable: the time of solidification, for instance, changes strongly in course of time. This made it desirable to investigate more

<sup>4</sup> Good photographs of such needles have been published by Geasner, *Kolloid-chem. Beiheft*, 1924, 19, 213.

thoroughly the influence of varied conditions as to rheopexy and thixotropy.

The first impression, that both thixotropic and rheoplectic behaviour were limited to a very narrow range of  $V_2O_5$  concentrations, did not prove to be correct. Sol A could be diluted to half its original concentration whilst remaining thixotropic and rheoplectic.

The change in course of the time  $t$  of  $\theta$  of a rheoplectic and thixotropic sol is shown in a typical experiment (Table I.).

Table II. shows the influence of varying the concentration of electrolyte ;  $t$  is the time elapsed after mixing.

TABLE II.—SOL A (0.15 PER CENT.  $V_2O_5$ ).

117 hours	liquid at least 60 hours	1½ hours	—	12 mins.	—	10 mins.

The influence of electrolyte concentration is marked and not simple. It is also important to add the electrolyte always in the same way in order to obtain the same results. The coagulation of sols is likewise often very sensitive to the rate at which the electrolyte is added. Obviously the same holds for thixotropy and rheopexy, which may both be considered as special, primary, stages of coagulation.

TABLE III.—THE SOLS CONTAINED 0.16 PER CENT.  $V_2O_5$  AND 125 m. MOL.  $LiCl$  (90 m. Mol. being added at once, the rest after 20 hours.)

33 days	12 mins.	30 secs.	22 mins.	45 secs.

The changes going on in course of time in these mixtures containing electrolytes also makes matters more complicated. One is probably dealing not only with changes caused by colloidal processes, but also with

the effects of chemical reactions.  $V_2O_5$  is known to form complex compounds with many acids<sup>8</sup> (notably  $H_2SO_4$ ,  $H_3PO_4$ ,  $H_3AsO_4$ , etc.); these compounds are highly soluble in water and hygroscopic. This, at least in part, most likely accounts for the instability of rheopectic  $V_2O_5$  sols containing  $H_2SO_4$ .

Other electrolytes than acids, for instance LiCl, seem to behave in a more simple fashion as to the influence of the time  $t$  (cf. Table III.). This is probably due to the fact that presumably no chemical change takes place. But with LiCl, also, the rheopectic mixtures are not indefinitely stable; they coagulate in the course of one or two months.

### III.

Previous attempts to use other electrolytes than acids for preparing rheopectic  $V_2O_5$  sols had failed. This was somewhat surprising. For it is known that thixotropic  $V_2O_5$  sols can be produced with various electrolytes, e.g., LiBr, NaCl, KCl, etc.<sup>9</sup> Here we have obviously another point of difference between thixotropy and rheopecty which needs explanation.

Now it is also known that KCl is not specially suitable for making stable thixotropic  $V_2O_5$  sols<sup>9</sup>; the proper range of electrolyte concentration is very narrow indeed and thixotropic sols prepared with KCl are coagulated in the majority of cases after 2 or 3 sol-gel transformations. Li-salts are definitely better: the range of electrolyte concentrations is broader, the thixotropic changes occur at higher electrolyte concentrations and generally need a longer time. The experiments, mentioned above, show that Li salts obviously favour both rheopectic and thixotropic solidification.

To find Li salts behaving in the same way as acids in acting upon a negative sol is extraordinary for, with most negative sols, the behaviour of Li salts is opposite to that of acids: Li salts being weaker coagulants than monovalent cations such as  $K^+$ ,  $NH_4^+$  ion, etc., whereas  $H^+$  ion is generally a much stronger coagulant than these cations.<sup>7</sup>

It has, however so far not been realised that  $V_2O_5$  sols belong to those very few cases where acids are very weak coagulants.<sup>8</sup> The other well-known case of this kind is Odén's sulphur sol,<sup>9</sup> which always contains pentathionic acid.<sup>10</sup> The table

TABLE IV. —COAGULATION VALUES.

Electrolyte.	Sol A.	Sol B.	Sol C.
LiCl	160	160	120
$Li_2SO_4 \cdot 2$	120	120	120
KCl	2.8	7.0	2.1
$K_2SO_4 \cdot 2$	8	12	8
$(NH_4)_2SO_4 \cdot 2$	very similar to $K_2SO_4$		
HCl	29	29	29
$HNO_3$	28	28	28
$HClO_4$	27	36(?)	27
$H_2SO_4 \cdot 2$	44	dissolution	33
		no coagulation

		no coagulation	
$H_3AsO_4 \cdot 3$	no coagulation, strong dissolution		
$CH_3COOH$		no effect	

of coagulation values (Table IV.) proves the truth of this assertion: the acids have indeed up to 10 times larger coagulation values than the K salts, and the Li salts still about 5 times higher ones.

<sup>7</sup> Cf. for instance, Freundlich, *Colloid and Capillary Chemistry*, p. 420.

<sup>8</sup> Ostermann (*Wissenschaft u. Industrie*, 1922, 1, 17) has investigated the coagulation of  $V_2O_5$  sols by HCl; he did not determine coagulation values, but was mainly interested in the ultramicroscopic behaviour of the process.

<sup>9</sup> Odén, *Nov. act. reg. soc. scient. Upsal.*, 1913, Ser. IV., 3, Nr. 4.

<sup>10</sup> Freundlich and Scholz, *Kolloidchem. Beiheft*, 1922, 16, 234.

The experiments were carried out in the usual manner with a  $V_2O_5$  sol having a concentration of 0.16 per cent. 0.5 c.c. of the sol were added to 0.5 c.c. of the electrolyte solution and thoroughly mixed. After waiting for 2 hours observations were taken. The minimum values to cause turbidity are given in terms of the concentration of the electrolyte (m. Mols./litre) present after addition of the sol; the latter then contained 0.08 per cent.  $V_2O_5$ . The three sols do not differ much as to coagulation values. The chemical action of the acids, their ability to dissolve  $V_2O_5$ , is specially pronounced in sol B, which contains by far the smallest particles; this was to be expected.

It is interesting to compare the coagulating values of the electrolytes in Table IV. with their respective ability to produce rheopexy. No rheopexy could be obtained with KCl,  $K_2SO_4$ ,  $(NH_4)_2SO_4$ . They had a strongly coagulating effect and within a narrow range of concentration thixotropic sols could be produced, when working very carefully. Acetic acid had no effect whatever upon sol A; it probably does not behave as a typical electrolyte. The behaviour of the other acids is remarkable. Rheopexy could be obtained with mono- and divalent acids, the suitable concentrations being the same as with  $H_2SO_4$ . Samples made up with monobasic acids, however, appear to be less stable than those containing  $H_2SO_4$ ; in some cases they were found to coagulate irreversibly after a few sol-gel transformations. As was mentioned above, the actions of acids is not merely due to coagulation; they also act chemically, dissolving  $V_2O_5$  and forming complex compounds. With tribasic acids the chemical action outweighs any coagulating effect, so as to make it sometimes difficult to determine the latter at all. Li salts were specially suitable for preparing rheoplectic sols.

#### IV.

It results from the preceding paragraph that only those electrolytes give rheoplectic sols which are weak coagulants. One cannot replace them by strongly coagulating electrolytes using a correspondingly smaller concentration. This seems to show that it is a special property of the weakly coagulating electrolytes which makes them capable of producing rheopexy. The main point is perhaps that these electrolytes are able to coat the  $V_2O_5$  particles with a strongly hydrated layer. With  $Li^+$  ion such an effect would be evident: it is certainly a strongly hydrated cation and is markedly adsorbed by the negatively charged  $V_2O_5$  particles. Not quite so obvious is the behaviour of the acids. It may most likely be attributed to the formation of complex compounds with  $V_2O_5$ . The latter are very soluble in water and hence may be considered as having a strong affinity to water. When these compounds are formed on the surface of the particles, they produce there a highly hydrated layer.<sup>11</sup>

A  $V_2O_5$  sol containing a small amount of the complex compound formed with an acid would be very similar to an Odén sulphur sol, where a layer of the strongly hydrophilic pentathionic acid is adsorbed on the sulphur particles; in their original state the latter would better be called hydrophobic.

The experiments of this paper do not permit final conclusions as to the mechanism of rheopexy. The following are perhaps probable: the special kind of movement used brings the fairly large, anisometric  $V_2O_5$  particles into a position, where the conditions of interaction are

<sup>11</sup> A good way of preparing stable rheoplectic  $V_2O_5$  sols might be to add, from the very start, a solution of the complex compound of  $V_2O_5$  with a suitable acid.

somewhat different than in the thixotropic sol, when it is left to itself. As was mentioned above, it has not been proved that the orientation of the particles parallel to each other, brought about by the gentle movement, is instrumental. It is quite possible that the particles may touch each other more easily and more closely, when moved, and then form strings and a kind of network. One is dealing with the same difficulty as one encounters, when trying to explain thixotropy.<sup>12</sup> In any event, in both cases a large amount of liquid may be interlocked and a solid gel is formed.

If, however, the particles are not coated with a hydrated layer, the repelling forces are not sufficiently strong to keep them apart: the movement used may favour a mechanical coagulation,<sup>13</sup> not a rheoplectic gel formation. This is what probably happens with salts such as KCl, etc., whereas with Li salts and acids the hydrated layer prevents true coagulation and allows a rheoplectic behaviour. Thus rheopexy appears to be, to a certain extent, an intermediate state between a stable sol and a coagulation caused by stirring; just as thixotropy may represent an intermediate state between a stable sol and a coagulation caused by electrolytes. There actually seems to exist a fairly close relation between rheopexy and mechanical coagulation.

The influence of hydrated layers upon rheopexy seems to show that one is not dealing with primary attracting forces between the particles, even if it should turn out that a close touch between the particles is the decisive factor, not orientation.

One influence, so far unmentioned, must be referred to, *viz.*, that of the  $\zeta$ -potential of the particles. In thixotropy it has to have an intermediate value between the high value in stable sols and the low one, when coagulation occurs. Rheopexy seems to be bound to an even narrower range of suitable  $\zeta$ -potentials.

### Summary.

1. Rheopexy, *i.e.*, the solidification of thixotropic sols by gentle and regular movement was investigated in  $V_2O_5$  sols containing electrolytes. Freshly prepared  $V_2O_5$  sols with amicroscopic particles were only thixotropic, not rheoplectic. But as soon as large, needle-shaped  $V_2O_5$  particles had been formed in the course of a long time or by careful treatment at higher temperature, the sols became rheoplectic.

2. Not all electrolytes are suitable for producing rheopexy in these sols: rheoplectic sols may be made with Li salts and acids, not with K and  $NH_4$  salts, though the latter can produce thixotropic  $V_2O_5$  sols. The special activity of Li salts and acids is probably due to the marked hydration of the  $Li^+$  ion, and to the fact that the acids can form strongly hydrated complex compounds on the surface of the particles.

3. Li salts and acids are weak coagulants for  $V_2O_5$  sols. This is an anomalous behaviour so far as acids are concerned, since negative sols are generally coagulated more strongly by  $H^+$  ion than by the other inorganic, monovalent cations.  $V_2O_5$  sol resembles in this respect Odén's sulphur sol.

4. Rheopexy is closely related to coagulation by stirring; it may be considered to be an intermediate state between a stable sol and one coagulated by stirring, just as thixotropy may in many cases be assumed

<sup>12</sup> Cf. for instance, Freundlich, *Thixotropy*, Paris, 1935, pp. 10-11.

## THE OXIDATION OF CARBON.

BY J. D. LAMBERT.

*Received 2nd December, 1935.*

*(Communicated by C. N. HINSHELWOOD.)*

It is well known that oxygen can undergo chemisorption on the surface of carbon to give some form of surface oxide layer. Schilow<sup>1</sup> and Kolthoff<sup>2</sup> have demonstrated the existence of different specific oxide complexes on the carbon surface, which are formed under definite conditions and show acidic or basic properties. Such surface oxides will clearly play some part in the oxidation process of carbon.

In order to investigate the kinetics of the primary oxidation process it is necessary to eliminate the effect of the rate of diffusion of gas to and from the surface. This may be done either by working with a small filament at temperatures of 800° to 1200° C. and at very low pressure, or with a large surface (granules) at normal pressures and at relatively low temperatures where the very slow surface reaction is the controlling factor. The experimental results which have been obtained by both methods are very varied, but may be divided into two main groups: on the one hand Langmuir<sup>3</sup> working with filaments at 950° C. found a formation of pure carbon dioxide by impact of oxygen molecules on the *clean* carbon surface—the process being *retarded* by formation of oxide layer: on the other hand Langmuir, working at higher temperatures, Sihvonen,<sup>4</sup> Eucken,<sup>5</sup> and Meyer,<sup>6,7</sup> working with filaments over a wide temperature range, and Rhead and Wheeler,<sup>8</sup> working with charcoal granules at temperatures in the neighbourhood of 500° C. found primary formation of *both* carbon dioxide and carbon monoxide by various different mechanisms involving the breakdown of surface oxide complexes. The

wide divergence between the results of different experimenters must be due either to difference in experimental conditions, or to difference in the nature of the carbon surface used. We have attempted to correlate different types of mechanism by investigating the oxidation of several different kinds of carbon under standard experimental conditions.

### Experimental Method.

The experimental method was to pass mixtures of oxygen and nitrogen at steady and accurately measured rates over a granular carbon packed in a silica tube, which was heated in an electric furnace, and to collect and analyse a sample of the gas coming off when a steady state was reached. The length of time for which the gas is in contact with the carbon was inversely proportional to the rate of flow and by measuring the percentage reaction at different flow-rates it was possible to obtain a curve showing the course of the reaction with time. The experiments were all conducted at atmospheric pressure, but the initial oxygen concentration could be varied by altering the proportions of oxygen and nitrogen in the mixture.

The apparatus is shown in Fig. 1(a). Oxygen and nitrogen were obtained from cylinders fitted with reducing valves and the flow-rates could be accurately adjusted and measured by adjustable blow-off bubblers "A" and venturi flow-meters "B."

The cylinder gases used were analysed from time to time and were always found to be at least 99.5 per cent. pure. The percentage compositions of mixtures of oxygen and nitrogen calculated from flow-meter readings agreed with those obtained by check analyses within 0.5

FIG. 1.

per cent. The carbon was contained in a silica tube, Fig. 1(b) specially designed to ensure a steady flow of preheated gas through the granules. The temperature was measured by a thermocouple inside the carbon bed and controlled to within  $\pm 1^\circ \text{C}$ . by hand adjustment or (in the later stages of the work) by a Cooke and Swallow automatic regulator. The reaction was not sufficiently rapid for the temperature to be affected by the heat developed in the combustion. Gas samples of 20 c.c. were collected over mercury in a collector shown in Fig. 1(c) which allowed the sample to be taken at constant pressure without appreciably disturbing the flow-rate. The gas analyses were made in an apparatus designed by B. Lambert (description not yet published). Approximately 20 c.c. of carbon granules were used in each set of experiments and the gas was passed at flow-rates varying between 2 c.c. per minute and 10 c.c. per minute. The attainment of a "steady state" after the setting of temperature and flow-rate was checked by taking samples at intervals of half an hour and analysing for carbon dioxide—agreement between the percentages of  $\text{CO}_2$  obtained by analysis of

two successive samples to within 0.5 per cent. being regarded as a sufficient criterion. The "steady state" was usually reached after about two hours: the accuracy of the experimental results was ensured either by analysing two successive samples as above, or by allowing at least three hours between setting and sampling. It was thus possible to obtain three or four readings in one day's "run." The error due to burning away of the carbon surface during this time was checked for each type of carbon by occasionally repeating the initial reading at the end of the day; the percentage reaction usually showed a steady decrease of 2 per cent. or less. A complete series of readings to demonstrate some particular point—course of reaction, oxygen concentration effect, or temperature coefficient—was always taken on a single day so as to eliminate as far as possible errors due to alteration in the carbon surface.

### Experimental Results.

Four kinds of carbon were used: steam-activated coconut charcoal granules, steam-activated anthracite granules, granules of pure graphite, and diamond dust. The coconut charcoal

FIG. 2.—Effect of Initial Oxygen Concentration.

and anthracite were clean, hard granules and so graded that different samples gave results which were almost quantitatively identical. The graphite granules were cut by hand from a lump of pure natural Ceylon graphite. The diamond dust was obtained commercially and ten grams were spread on clean asbestos wool so as to occupy a convenient volume. Each sample of carbon was heated to 1000° C. in a current of nitrogen for several hours before use so as to remove moisture. The term "percentage reaction" is used to indicate the percentage of the oxygen present in the initial gas mixture which has been converted to carbon dioxide or carbon monoxide. The temperature range of each set of experiments is arbitrarily determined by the relation between the rate of reaction and the available rates of flow.

**Coconut Charcoal** burnt in the neighbourhood of 250° C. giving carbon dioxide with a trace of carbon monoxide.

The Course of Reaction is shown by Table I. and approximates closely to first order.

The Effect of Initial Oxygen Concentration is shown in Fig. 2. For a true first order reaction the percentage reaction in a given time is independent of the initial oxygen concentration. This is clearly not so in the

FIG. 3.—Effect of Temperature.

present case and the deviations are such as would be accounted for by supposing either that the reaction is of less than first order with respect to oxygen—or that it is retarded by carbon dioxide.

The effect of carbon dioxide was investigated by comparing the percentage reaction given by oxygen diluted by nitrogen with that given by oxygen diluted by the same percentage of carbon dioxide under identical conditions. The results of a series designed to show both the retardation by carbon dioxide and the effect of initial oxygen concentration (see discussion later) are shown in Table II. It was very difficult to obtain steady values with carbon dioxide as diluent and the results are not quantitatively reproducible, but there is clearly a small retardation by carbon dioxide.

The Effect of Temperature is shown in Fig. 3. Values of the reaction constant " $k$ " were calculated on the assumption that the reaction follows a first order course and  $\log k$  was plotted against the reciprocal of the absolute temperature. The points fell closely on a straight line of slope corresponding to an Energy of Activation of 29,000 Cal. The close agreement with Arrhenius' Law and the high value of  $E$  indicate that the experimental results are real measurements of a true chemical reaction and are not influenced by accidents of flow and diffusion.

**Graphite and Diamond** both burn to pure carbon dioxide in the neighbourhood of 400° C. and 500° C. respectively. The kinetics are similar to those obtained with coconut charcoal. The experimental results are shown in Figs 2 and 3 and Tables I. and II.

### Discussion of the Kinetics of the Oxidation of Coconut Charcoal, Graphite and Diamond.

These three reactions are very similar and all show the same apparent discrepancy between an accurately first order course of reaction and an effect of initial oxygen concentration which tends strongly to zero order. It is possible to develop a quantitative theory which will account for this on the basis of Langmuir's idea<sup>3</sup> of a direct formation of carbon dioxide, the reaction being retarded by the simultaneous formation of a stable surface oxide layer. We must assume *in addition* that a similar retarding layer is *also* formed by carbon dioxide. If it be further assumed that carbon dioxide *formed in the reaction* is retained by the surface and held approximately as firmly as the oxygen in the retarding film we may obtain for the rate of reaction

$$\frac{d[\text{CO}_2]}{dt} = \frac{k[\text{O}_2]}{1 + b\{[\text{O}_2] + [\text{CO}_2]\}} \quad (1)$$

Since  $\text{O}_2 + \text{C} \rightarrow \text{CO}_2$  the factor  $\{[\text{O}_2] + [\text{CO}_2]\}$  is equal to the initial oxygen concentration and constant throughout the course of the reaction, which will obey a first order expression :

$$\frac{d[\text{CO}_2]}{dt} = \frac{k[\text{O}_2]}{1 + \text{const.}} = k'[\text{O}_2].$$

When the initial oxygen concentration is varied, if " $a$ " be the initial oxygen concentration and " $x$ " the amount which has reacted at time " $t$ ," we may write

$$\frac{dx}{dt} = \frac{k(a - x)}{1 + ba}.$$

This integrates to give

$$k = \frac{1 + ba}{t} \ln \frac{a}{a - x}.$$

This contains two unknown constants " $k$ " and " $b$ " and may be tested by solving for " $b$ " and " $k$ " from two experimental settings and using these values to calculate for a third oxygen concentration a theoretical value of " $x$ " which may be compared with the experimental result. The agreement obtained is satisfactory as shown in Table III.

TABLE III.—THE EXPERIMENTAL VALUES TAKEN ARE THOSE SHOWN IN FIG. 2.

Type of Carbon.	Values used to Calculate " $b$ " and " $k$ ."		" $b$ ."	" $k$ ."	Initial O <sub>2</sub> Concentration to be Tested.	Percentage Reaction.	
						Calculated.	Observed.
Coconut Charcoal .	40	30.7	0.027	3.84	60	25.3	25.8
	100	18.6					
Graphite . . .	100	14.5	0.064	5.28	60	21.4	21.8
	30	32.8					
Diamond . . .	100	23.5	0.012	3.01	60	29.1	29.5
	30	35.5					

The assumption that carbon dioxide *formed in the reaction* is adsorbed with about the same firmness as oxygen would hardly be expected to apply to carbon dioxide added externally. The experimentally observed retardation by carbon dioxide (Table II.) is indefinite and much less than that demanded by equation (i), which would predict the percentage reaction for any mixture of oxygen and carbon dioxide to be the same as that for pure oxygen. In the case of diamond, which being more homogeneous might be expected to show simpler adsorption characteristics than charcoal or graphite, there is some approximation to the theoretically predicted retardation.

### Molecular Statistics of the Reaction.

The actual rate of a heterogeneous gas reaction at a given temperature is determined by the number of gas molecules striking the surface in unit time and by the activation energy. It may be shown from the kinetic theory that :

$$\frac{1}{3} \frac{v \lambda}{A} = e^{-E/RT} \quad (2)$$

Where " $x$ " is the fraction of molecules which react when a gas streams at velocity  $v$  cm./sec. over a surface of area  $A$  sq. cm. This equation cannot be applied quantitatively to our results in default of any accurate knowledge of the surface areas used, but a *qualitative* test of the validity of the energies of activation obtained may be made by calculating  $A$  from the observed values of  $E$  and  $x$  and observing whether the results are plausible. An abnormally large value of  $A$  will indicate that the reaction takes place much faster than would be expected from its energy of activation—and vice versa. The results of the calculation are shown in Table IV.

It is clear that for graphite and diamond the calculated values of  $A$  are absurdly high, showing that the reaction takes place much faster than its energy of activation should permit. It is inconceivable that

TABLE IV.

Type of Carbon.	<i>E</i> .	<i>A</i> (Calculated).	<i>A</i> (Measured in Other Ways).
Coconut Charcoal .	29,000 Cal.	$1.6 \times 10^4 \text{ cm.}^2$	Rough values given in the literature—calculated from adsorption data. $1.8 \times 10^5 \text{ cm.}^2$ $1.46 \times 10^7 \text{ cm.}^2$
Anthracite . . .	31,000 Cal.	$5.4 \times 10^4 \text{ cm.}^2$	Adsorptive capacity for vapours $\frac{1}{3}$ that of coconut charcoal.
Graphite . . .	49,000 Cal.	$9.15 \times 10^8 \text{ cm.}^2$	External surface of granules estimated from average granular size. $2.7 \times 10^2 \text{ cm.}^2$
Diamond . . .	44,000 Cal.	$9.0 \times 10^8 \text{ cm.}^2$	

the surface area of graphite granules, or even of diamond powder should be larger than that of highly active charcoal and the effect can only be explained if it be supposed that *E* is *not* the true energy of activation in these two cases, but contains other terms which give the reaction an abnormally high temperature coefficient. There are two possibilities :

(i) A retarding layer begins to evaporate off the surface at higher temperatures but is stable at the lower temperatures of the coconut charcoal oxidation. (It is interesting to note that the "Oxide C" described by Schilow *begins* to be thermally unstable at temperatures above 400° C.).

(ii) The available surface increases at higher temperatures owing to the opening up of cracks.

Calculation of an energy of activation for the graphite oxidation by equation (2) from the measured surface area of the graphite granules, which is probably of the right order, gives a value of 27,000 Cal. (*cf.* *E* = 29,000 Cal. for coconut charcoal). This suggests that the two oxidation processes are essentially the same in both kinetics and energy but that the temperature coefficient for the oxidation of graphite is modified by the type of effect described.

### Experimental Results with Anthracite.

The anthracite granules burnt at about 400° C. to give a mixture of carbon dioxide and carbon monoxide. In the tables below "percentage reaction to carbon monoxide" is the percentage of *oxygen* converted to carbon monoxide, which is equal to *half* the carbon monoxide formed, since  $\text{O}_2 + \text{C} \rightarrow 2\text{CO}$  (a correction is applied for the volume increase).

The Course of Reaction is shown in Fig. 4.

The *total* reaction gives a first order curve, but the proportion of carbon dioxide to carbon monoxide increases rapidly with time.

The Effect of Initial Oxygen Concentration is shown in Fig. 5. This shows a very close approximation to the theoretical behaviour of a first order reaction and the  $\text{CO}_2 : \text{CO}$  ratio is independent of the initial oxygen concentration.

The Effect of Temperature is shown in Fig. 3. Values of *k* were calculated for the total percentage reaction, assuming a first order course, and log *k* plotted against the reciprocal of  $\theta_{\text{Ab.}}$  gave a very straight line corresponding to *E* = 31,000 Cal.

In order to test whether carbon monoxide is a *primary product* a mixture of carbon dioxide and nitrogen was passed over the anthracite at 385° C. No trace of carbon monoxide could be detected in the product.

This is to be expected since even at 500° C.  $k = \frac{[\text{CO}]^2}{[\text{CO}_2]}$  for the reaction

FIG. 4.—Course of Reaction with Time.

$\text{CO}_2 + \text{C} \rightarrow 2\text{CO}$  is  $10^{-10.5}$ . It would appear that the primary process is a reaction of first order with respect to oxygen giving a mixture of carbon dioxide and carbon monoxide, or possibly pure carbon monoxide; and that the increase in the ratio  $\text{CO}_2 : \text{CO}$  with time is due to the reaction

FIG. 5.—Effect of Initial Oxygen Concentration.

$2\text{CO} \rightarrow \text{C} + \text{CO}_2$  which is thermodynamically favoured at this temperature and which has been shown by Rhead and Wheeler to occur fairly rapidly under these conditions. (The effect cannot be due to further oxidation

of CO to CO<sub>2</sub> as this would mask the simple first order course of the total reaction—and furthermore as the CO<sub>2</sub>:CO ratio is independent of the initial oxygen concentration—see Figs. 4 and 5.)

### Experiments on Artificially Treated Charcoals.

It has been shown that graphite and diamond, the purest forms of carbon used, give pure carbon dioxide on oxidation at temperatures of 440° to 480° C.; while anthracite, which is certainly impure, gives a mixture of carbon dioxide and carbon monoxide at 300° C. This suggests that the primary production of carbon monoxide may be due to the presence of some special form of impurity on the carbon surface. Coconut charcoal, which is oxidised at 250° C. to give carbon dioxide with a trace of carbon monoxide and shows the same kinetics as graphite and diamond can be regarded as containing only a trace of this impurity. It is noteworthy that the anthracite, whose energy of activation (31,000 Cal.) is only slightly higher than that of coconut charcoal (29,000 Cal.); and which probably has a similar surface area, oxidises under experimental conditions at a very much higher temperature. It would appear from this that only a portion of the surface is effective. Furthermore while the kinetics of the oxidation of coconut charcoal, graphite and diamond involve a very marked retardation by increased oxygen concentration (Fig. 2), this is almost absent in the anthracite (Fig. 5). We can account for this by supposing that in anthracite the simple, direct formation of carbon dioxide found in the other three cases is practically suppressed by the blocking of those portions of the surface where this is possible. Instead there is a slower reaction in which both carbon dioxide and carbon monoxide are produced by a different mechanism which probably involves the breakdown of a surface oxide complex. This latter process would appear to be *catalysed* in the anthracite and not merely occasioned by the raising of the reaction temperature, as coconut charcoal still gives only a trace of carbon monoxide when oxidised at 400° C. The anthracite therefore differs from the other forms of carbon in that those portions of the surface where direct formation of pure carbon dioxide can take place are blocked, whilst the primary formation of carbon monoxide and carbon dioxide by a different type of process is catalysed.

Attempts were made to treat the coconut charcoal with a substance which would exert this combined *poisoning* and *promoting* effect to give an artificial product reproducing the behaviour of anthracite. The presence of moisture, which has been supposed by some workers to have a profound effect on the interaction of carbon and oxygen, merely retarded the formation of carbon dioxide (presumably by blocking a portion of the carbon surface) without altering either the energy of activation of the reaction or the proportion of carbon monoxide formed. Sodium and Potassium Carbonates (although well known for their influence on the burning of charcoals in general) were similarly ineffective under these conditions. The anthracite was known to contain *iron*, and it was found that after treating a sample of coconut charcoal (which normally burnt at 250° C. under experimental conditions to give carbon dioxide with a trace of carbon monoxide) by "cleaning out" at 1000° C. in a nitrogen stream, boiling in ferric chloride solution, and heating in nitrogen again to remove water, hydrochloric acid, and excess ferric chloride, oxidation at a rate comparable with the original took place only at 400° C., to give a mixture of carbon dioxide and carbon monoxide. The kinetics were investigated and found to be very similar to the kinetics for the oxidation of anthracite.

The Course of Reaction is shown by Fig. 4. The rate falls off with time slightly more rapidly than for a first order reaction. The ratio of carbon dioxide to carbon monoxide increases with time as in the case of anthracite.

The Effect of Initial Oxygen Concentration is shown in Fig. 5 and corresponds accurately to a first order reaction—as with anthracite.

The Effect of Temperature is shown in Fig. 3  $\log k$  plotted against the reciprocal of the absolute temperature gives a straight line corresponding to  $E = 30,400$  Cal. (cf.  $E$  for anthracite 31,000 Cal.).

The behaviour of two different iron-treated samples of coconut charcoal was very carefully investigated and both showed the same close resemblance to anthracite. The effect only occurs when a charcoal sample *which has been "cleaned" by heating to 1000° C. in nitrogen* is treated with ferric chloride solution. If an uncleaned sample is so treated the oxidation is considerably retarded (the sample burnt under experimental conditions at 350° C.) but no appreciable amount of carbon monoxide is formed. It would appear that the "promotion" depends on intimate adsorption of iron on the most active points of the charcoal surface.

### Discussion.

General consideration of the literature shows that two distinct types of process are possible in the oxidation of carbon (see introduction to this paper).

(1) Direct formation of carbon dioxide by impact of oxygen molecules on the *clean* carbon surface, a process which is retarded by the presence of surface oxide layer.

(2) The primary formation of both carbon dioxide and carbon monoxide by mechanisms involving the breakdown of surface oxide layer either spontaneously, or by impact of oxygen molecules from the gas.

Under our experimental conditions pure carbon (whether graphite or diamond) shows exclusively process (1). Process (2) only occurs in the presence of iron (other catalysts may of course have a similar effect) which also poisons the surface for process (1). The action of the catalyst is possibly to decrease the stability of the surface oxide so that it breaks down under the impact of oxygen molecules from the gas to give a mixture of carbon dioxide and carbon monoxide at a rate proportional to the oxygen concentration. A similar decrease in stability may well occur at higher temperatures without the presence of a catalyst. If this is so, process (2) will operate on *pure* carbon at higher temperatures as was demonstrated by Langmuir<sup>2</sup> who found that on a pure carbon filament at 950° C. process (1) occurs exclusively whilst at temperatures above 1430° C. process (2) begins to operate. We cannot at the present stage in our investigations suggest a detailed mechanism for process (2) in default of information as to the proportions in which carbon dioxide and carbon monoxide are primarily formed. In view of the diversity of surface oxides which can exist<sup>1</sup> it may be that several different mechanisms are possible under varying conditions.

### Summary.

Two distinct types of process appear to be possible in the oxidation of carbon:

- (1) Direct formation of carbon dioxide by impact of oxygen molecules on a clean carbon surface.
- (2) Primary formation of both carbon dioxide and carbon monoxide by the breakdown of surface oxide complexes.

The kinetics of the oxidation of several kinds of carbon have been investigated in the temperature range 250°–500° C. by a dynamic method, with a view to correlating the different mechanisms. Pure graphite and diamond showed exclusively process (1). An activated coconut charcoal showed process (1) with a trace of process (2). Activated anthracite,

containing a considerable amount of iron showed exclusively process (2). Treatment of the coconut charcoal with ferric chloride under suitable conditions gave an artificial product whose behaviour on oxidation reproduced very closely that of the anthracite. These results are discussed in relation to the work of other authors.

The author is very grateful to Mr. C. N. Hinshelwood for his interest in the whole work; to Dr. B. Lambert for advice on the experimental technique and for the loan of apparatus; and to Mr. J. H. Strawson who performed some of the experiments.

He is indebted to Imperial Chemical Industries (Alkali) Limited, for two silica combustion tubes.

## STUDIES ON SOL-GEL TRANSFORMATIONS. II. DILATOMETRIC INVESTIGATIONS ON IRON HYDROXIDE, GELATIN, METHYL CELLULOSE, SILICIC ACID AND VISCOSE.

BY ERICH HEYMANN.

*Received 19th November, 1935.*

### I. Introduction.

It is still a matter of speculation as to the nature of the changes that occur in a colloidal system, when it is transformed from a sol into a gel (jelly), especially whether any changes in hydration of the colloidal particles occur during such a process. Some time ago a paper was published,<sup>1</sup> in which the "inverse" sol-gel transformation of methyl cellulose solutions, forming a reversible gel on heating, was dealt with. The change of the investigated physical (viscosity, density) and chemical (lyotropic series of ions) properties indicated<sup>1</sup> that the gel formation was accompanied by a reversible decrease in hydration of the particles: the viscosity, for instance, measured at constant temperature, at first decreased reversibly and showed the usual increase due to gelation only after a time. This initial reversible viscosity decrease can be explained by a decrease in hydration, since no decrease in particle size takes place during this sol-gel transformation. The volume, investigated in a sensitive dilatometer at constant temperature, increased during the sol-gel transformation. Since we have to assume that hydration water, bound by van der Waals' forces to the particles, has a higher density than free water, this also suggests that the particles become less hydrated during the formation of a methyl cellulose gel.

A comparison of sol-gel transformations of various types of systems in respect to the volume change shows that all possible types can be realised experimentally: systems with no volume change (iron hydroxide), systems which show a decrease in volume (agar, gelatin), and systems which show an increase in volume (methyl cellulose, silicic acid).

<sup>1</sup> E. Heymann, *Trans. Faraday Soc.*, 1935, **31**, 846.

An attempt is made to derive from these experimental facts some information about the structural changes which occur during the various sol-gel transformations.

The total volume contraction, which occurs when a hydrophilic colloid is dissolved in a liquid with the formation of a sol or a gel has been determined many times, *e.g.*, by H. Quincke,<sup>2</sup> (egg albumin), H. Rodewald<sup>3</sup> (starch), C. Davis and E. Oakes,<sup>4</sup> H. Chick and C. H. Martin<sup>5</sup> (proteins), J. R. Katz<sup>6</sup> (casein, nuclein, starch), A. Taffel<sup>7</sup> (gelatin), The Svedberg<sup>8</sup> (gelatin), W. J. Mardles<sup>9</sup> (organosols), and H. A. Neville and E. R. Theis<sup>10</sup> (gelatin). The very small volume changes, however, which occur when a sol is transformed into a gel, have only been measured by W. J. Mardles (acetyl cellulose), by K. Krishnamurti<sup>11</sup> (agar), and by the author.<sup>1</sup>

The volume change measurements of sol-gel transformations require a much more sensitive dilatometric technique than the determination of the total volume change during the dissolution of a colloid. A sensitive mercury dilatometer for this purpose is described in the next paragraph. The systems for investigations must show a hysteresis, which allows observations on the transformation to be made over a period of hours or days, in order that the time taken for the dilatometer to acquire the temperature of the thermostat can be neglected.

## II. Volume Changes during Sol-gel Transformations.

### (a) Experimental.

A sensitive dilatometer has already been described.<sup>1</sup> Its main advantage consists in the fact that the sol is only in part I., whereas the whole of part II., including the capillary (b) is filled with mercury (Fig. 1). Vacuum grease was used for coating the tap (c) and the key pressed in by a taut rubber band. This method proved to be very satisfactory. With practice leakage through the tap never occurred. The measurements were carried out in an electrically heated water-thermostat, the temperature of which had a maximum variation of  $0.003$  to  $0.004^{\circ}$ . The volume of the sol was about 80 c.c., the radius of the capillary 0.23 mm.; thus a length of 1 cm. in the capillary corresponded to a volume change of 0.0016 c.c. Consequently the smallest volume change, which could be detected with certainty (corresponding to a change of meniscus of 0.1 cm.) was 0.0002 %. As the volume changes usually measured in the investigated systems were between 0.002 and 0.01 % of the total volume (corresponding to a change of height of meniscus from 0.6 to 7.5 cm.) the accuracy of a

<sup>9</sup> H. A. Neville and E. R. Theis, *Coll. Symp. Monogr.*, 1930, 7, 41.

<sup>10</sup> K. Krishnamurti, *Current Science*, 1934, 2, 35.

determination of change in volume was about 1.5 to 12 %, according to the magnitude of the volume change measured.

In many systems, however, the changes in volume are larger than 0.01 %. In these cases ordinary dilatometers without mercury were used. The dimensions varied according to the magnitude of the effect. The capillaries had radii between 0.16 and 0.35 mm., whereas the volume was usually between 30 and 70 c.c. In all these cases, however, a layer of paraffin oil was put above the sol and in the capillary, since it was necessary to prevent the solidifying sol entering the capillary. The ordinary dilatometers were used for investigating the sol-gel transformations of silicic acid and the maturing of viscose, whereas the sensitive mercury dilatometer was used for methyl cellulose, gelatin and iron hydroxide.

In all experiments it was ensured that the temperature equilibrium between the dilatometer and the thermostat had been reached before the first reading was taken. Moreover, precautions were taken to avoid the formation of air bubbles.

### (b) Reversible Sol-gel Transformations.

One dilatometric experiment on methyl cellulose (containing 35.4 % methoxyl) has already been described.<sup>1</sup> Thus only the results of the continued experiments will be here described. In series I. the solutions were aged at 35.7°, where the sol is transformed into a very soft gel over a period of two days. In series II. the volume of the sol was measured in the dilatometer at 34.5°, then the dilatometer was transferred into a bath at 55° for half an hour, when the gel was rapidly formed, afterwards the volume of the gel was measured at the same temperature at which the volume of the sol had been measured, namely, 34.5°. The difference in volume between the sol and the gel, obtained in this way was usually larger than in the case of method I.; the reason is that with method II. a stiffer gel is obtained than with method I.

The concentration of methyl cellulose was 1.62 %, the sols containing 0.1 mol.  $K_2SO_4$  in order to lower the transformation temperature for experimental convenience.

It can be seen from the results, given in Table I., that the formation

TABLE I.—VOLUME: 80 c.c.; RADIUS OF THE CAPILLARY: 0.23 mm.

Method.	Difference in Meniscus in cm.	Observed Volume Change.		Volume Change in c.c. Per 100 g. Methyl Cellulose.

	0.98			
	0.98			

of a methyl cellulose gel from the sol is accompanied by a volume increase of 0.08 to 0.13 c.c. per 100 g. solid methyl cellulose.

Several series of experiments were carried out with gelatin solutions and the volume change was measured in relation to the concentration of the gelatin and to

the  $p_H$ . Electrodialysed gelatin was used. In this system the volume decreases during the sol-gel transformation. The experiments were carried out as follows. The solution was filled into the dilatometer, then heated to about 50° to be sure that the whole mass was liquid and then placed in the thermostat at a temperature of 22.5°, where the gel formation occurred slowly. The main volume decrease took place within the first few hours; but after the sol had set to a gel the volume decrease

continued for some time. After two days the volume did not change further to any appreciable extent. If the dilatometer with the gel was again heated and replaced in the thermostat the same curve for the volume decrease was obtained. This could be repeated at will.

In Fig. 2 the curves (*a* and *b*) of two experiments show that the reproducibility of the results is fairly good. Curve *c* was obtained, after the dilatometer was placed in ice water, when a stiff gel is formed, and then replaced in the thermostat at 22.5°. It shows that the equilibrium volume of the gel, obtained in this way, is only very slightly below the volumes reached when the sol was transformed into a gel at 22.5° in two days; thus no further, appreciable volume change can be expected after this period.

FIG. 2.

Since the first reading has to be taken after the dilatometer has remained in the thermostat for half an hour, the first stages of the transformation cannot be observed and, therefore, the actual volume change may be somewhat larger than the measured one. From Table II. it can be seen that the volume decrease is proportional to the concentration. Furthermore it is independent of the  $p_H$  within the limits from 3.8 to 8.8. The volume decrease per 100 g. gelatin is  $-0.05$  to  $-0.06$  c.c.

TABLE II.

	1.60	80	$-0.0026$	$-0.0033$	$-0.056$

Many experiments were carried out with several thixotropic iron hydroxide sols. One, with a 0.44 % sol (prepared according to Graham's method), will be referred to, the sol being made thixotropic by adding a small amount of sodium chloride. It can be seen from Table III. that no change of volume occurs during the sol-gel transformation, the meniscus of the dilatometer remaining stationary during the whole experiment.

If we assume that a volume change equivalent to the maximum experimental error occurred, the

volume change per 100 g. iron hydroxide would be 0.001 c.c., a value 50 times smaller than that found for gelatin and 100 times smaller than for methyl cellulose. Consequently the volume change (if any) is practically negligible in thixotropic iron hydroxide sols.

### (c) Irreversible Sol-gel Transformations.

A very well-known example of an irreversible sol-gel transformation is the formation of silicic acid gels. If solutions of water glass and hydrochloric acid are mixed in suitable proportions, solutions of silicic acid are obtained which are transformed into gels after several hours. There is much information from other investigations (F. Mylius and E. Groschuff,<sup>12</sup> R. Willstätter, K. Kraut and K. Lobinger<sup>13</sup>) concerning the chemical and physical processes in such systems. At first,

molecular silicic acid is formed, which is quickly polymerised with the liberation of water ("chemical dehydration") to higher molecular products (polysilicic acids) and finally to colloidal particles. It seemed of interest to investigate such a system by the dilatometric method.

For the experiments water glass solutions, which contained about 12 %  $\text{SiO}_2$  were used, the ratio  $\text{SiO}_2$  to Na being 1 to 0.85. When such mixtures were observed in the dilatometer, a very quick increase in volume of considerable magnitude was noted within the first few hours. After 3 hours, for instance, the volume had increased by 0.028 %. After this, gel formation began and was complete in about 24 hours, when a clear jelly was obtained, the volume having increased by about 0.06 %. The volume of the so formed gel increased then more slowly; a change of 0.08 % being noted after 10 days and of 0.11 % (*i.e.*, a volume increase of 1.5 c.c. per 100 g.  $\text{SiO}_2$ ) after 3 months. Even after 5 months no final value was reached, the volume increasing still further, but with decreasing velocity. The gels became more and more opalescent and syneresis (about 13 %) was observed. A second mixture showed the same behaviour.

FIG. 3.

(Table IV.) The volume changes in this system are of quite a different order of magnitude compared with those of the previous systems. They are about 10 to 20 times larger.

The last system investigated was a solution of viscose. This system is more complex than the silicic acid gel. It was, however, investigated because of its technical interest.

50 g. cellulose (dense wood pulp)<sup>14</sup> was treated with an 18 % sodium hydroxide solution for about 20 hours. Then the liquid was pressed out until the remaining solid had a weight of about 150 g. This alkali cellulose was aged for 2 days, then 26 g. of carbon disulphide were added and the xanthogenate was formed within 3 hours. The whole mass was now dissolved in 7.2 % sodium hydroxide. The "maturing" of the viscose then commenced. The solution became less viscous at first, then the viscosity increased considerably until a gel was formed, and this finally underwent syneresis.

<sup>14</sup> I am greatly indebted to Dr. Weir (I.C.I. Ltd., Stevenston) for supplying me with a larger quantity of this substance.

This system was measured in the dilatometer. At first the volume decreased rapidly. Then, shortly before the gel formation occurred, the curve changed its direction and the volume increased. This volume increase continued, though slowly. Even after 3 months it did not come to a limiting value. The measured volume changes were of the same order of magnitude as those found with silicic acid solutions (Fig. 3).

### III. Volume Change, Hydration and Structural Changes in Reversible Sol-gel Transformations.

There is every likelihood that the volume changes in this group of transformations must be attributed to changes in hydration of the colloidal particles. Since the water bound by secondary forces to the particles has a smaller specific volume than the free water, a volume increase during the transformation accounts for a decrease in hydration. It is very probable that, by measuring volume changes, only that part of the hydration can be distinguished which is caused by an attraction of some kind ("adsorption solvation" by van der Waals and dipole forces; "chemical solvation"), whereas any changes in hydration caused by a mere change in immobilisation of water molecules for purely stereo-metrical reasons cannot be detected in this way.

The justification for these assumptions is given by the fact that hydrophilic colloids allowed to dissolve or to swell in water, cause a considerable decrease in volume of the total system, the water of the hydration layer thus undergoing a process of compression as a result of the attractive forces between the colloidal particles and the water dipoles.

The volume change that occurs during the sol-gel transformation is 50 to 100 times smaller than the volume contraction, which is found when the solid colloid swells or becomes dissolved in the liquid. For instance the swelling of gelatin in water causes a volume decrease of the total system of 5 to 7 c.c. per 100 g. gelatin (Thé Svedberg,<sup>6</sup> A. Taffel<sup>7</sup>). The volume change during the sol-gel transformation of gelatin, however, is only about 0.06 c.c. per 100 g. gelatin. In the system methyl cellulose-water the volume increase during the sol-gel transformation is 0.13 c.c. per 100 g. solid methyl cellulose. This is about 2 % of the volume contraction that occurs, when methyl cellulose is dissolved in water (7 to 8 c.c. per 100 g. solid methyl cellulose, according to preliminary experiments<sup>15</sup>). Thus in both systems the change in hydration during the sol-gel transformation is only a few per cent. of the total hydration.

If we speak in terms of hydration we have, however, to remember that there is no quantitative definition of this term, since the first liquid molecules are bound with a much higher energy than the later ones, and that there is no marked limit to the hydration layer, but a more or less smooth transition to the free water. It is interesting in this connection that the differential heat of swelling decreases gradually with swelling (J. R. Katz<sup>6</sup>).

In the thixotropic iron hydroxide sols no volume change can be detected during the sol-gel transformation, although the technique enables a volume change as small as 0.0002 % of the total volume to be noted. We have, therefore, to assume that there is no change in hydration during the sol-gel transformation of this system. This result is easily understandable. In these thixotropic systems the sol state and the

<sup>15</sup> Not yet published.

gel state are very much alike, both existing at the same temperature, the latter being transformed into the former by comparatively small mechanical forces (H. Freundlich<sup>10</sup>).

The "inverse" sol-gel transformation of methyl cellulose, investigated at constant temperature, is accompanied by an increase in volume. Thus the particles become less hydrated whilst the gel is formed. In consequence of this decrease in hydration, large, probably anisometric, coagulates are formed, which build up a loose network, the gel, if the concentration is high enough. H. Staudinger and O. Schweitzer<sup>17</sup> attribute the decrease in hydration to a decomposition of a methyl cellulose-oxonium-hydroxide, which is decomposed, when the temperature is raised. The gel formation of acetyl cellulose in organic liquids is also accompanied by a volume increase (W. T. Mardles<sup>9</sup>).

The opposite behaviour is shown in the sol-gel transformations of gelatin, according to the measurements described in this paper, and of agar, according to the investigations of K. Krishnamurti.<sup>11</sup> The transformation, investigated at constant temperature, is accompanied by a decrease in volume and, consequently, it can be assumed that hydration increases. This assumption is in agreement with the experiments of A. Taffel and of Th   Svedberg, who found that the volume contraction, which occurs when gelatin is dissolved in water, is larger at lower temperatures, where a gel is formed, than at higher ones, where sol formation occurs.

When an isoelectric gelatin sol sets to a gel, the gelatin molecules come nearer together and aggregation occurs to a certain degree, as indicated by ultramicroscopic investigations (W. Bachmann<sup>18</sup> and K. Krishnamurti<sup>19</sup>) and by measurements of the scattering of light (F. G. Donnan and K. Krishnamurti<sup>19</sup>). It seems likely that the equilibrium between the gelatin molecules and the polymolecular aggregates is shifted in the direction of the aggregates, when the gel is formed. The gelatin molecules are arranged in these aggregates (micelles) with a certain regularity, since the X-ray diagrams of the gels show interferences (J. R. Katz, J. C. Derkson and W. F. Bon<sup>20</sup>). But it is known from Bungenberg de Jong's<sup>21</sup> and from Katz' investigations, that this aggregation is not accompanied by a dehydration. In fact the volume change measurements show that hydration increases slightly during this process. This has already been suggested by Katz and Derkson. Aggregation and increase in hydration are, however, not related to each other, for, whereas the amount of aggregation is dependent on the  $p_H$ , the increase in hydration is independent of the  $p_H$ .

Only one fact seems at first to disagree with the assumption of a change in hydration during the sol-gel transformation of gelatin. The dielectric constant, measured by Kistler,<sup>22</sup> does not change during this process. However, it appears doubtful whether this method is sufficiently sensitive to detect a small change in hydration. For we have

<sup>22</sup> G. S. Kistler, *J. phys. Chem.*, 1931, **35**, 815.

seen that the hydration change during the sol-gel transformation is only a few per cent. of the total hydration. The effect of the total hydration on the dielectric constant corresponds to the difference between the dielectric constant of water (80) and that of a gelatin solution in a region of wave-length, where the gelatin dipoles do not contribute to the orientation polarisation. This difference is 2 to 3 units for a 0.9 % solution (J. Errera<sup>23</sup>). Consequently we have to expect for the sol-gel transformation of a 5 % gelatin solution a decrease in dielectric constant not greater than 0.2 units. This is probably below the limit of accuracy of dielectric constant measurements in systems with conductivity.

One might object that the volume changes observed during the sol-gel transformations of methyl cellulose, agar and gelatin are not necessarily connected with a change in hydration, but that they are the result of an aggregation of the colloidal particles. In this case, however, one would have to assume that the aggregation causes a volume increase in the case of methyl cellulose and a volume decrease in the case of gelatin and agar; a behaviour which would not be easily understandable. There are, moreover, other reasons which make such assumptions very unlikely.

(1) In the case of methyl cellulose a decrease of hydration of the particles during the sol-gel transformation seems likely not only as a result of the volume change measurements. The minimum in the isothermal viscosity curve as well as the influence of the lyotropic series of ions also indicate that a decrease in hydration occurs in this system (E. Heymann). Moreover, a decrease in hydration has to be expected for chemical reasons (Staudinger and Schweitzer).

(2) In the system gelatin-water it has been found by measurements of the scattering of light (Kraemer and Dexter<sup>24</sup>) and of the sedimentation velocity in the ultracentrifuge (Krishnamurti), that particle aggregation does not occur if the  $p_H$  is larger than 7.5 and smaller than 4. Thus if the volume decrease during the gel formation were due to aggregation, it should be dependent on the  $p_H$  and it should have a maximum at the isoelectric point. The measurements mentioned in section II. show, however, that the volume decrease is independent of the  $p_H$ . To add further point to these arguments, it would, however, be interesting to investigate the X-ray spectra during the gel formation of gelatin (Katz) at various  $H^+$  ion concentrations.

#### IV. Physical and Chemical Changes during Irreversible Sol-gel Transformations (Silicic Acid, Viscose).

Here the formation of a gel is in many cases the result of a chemical reaction in a solution where a colloidal product is formed. If the volume changes of such transformations are to be investigated, care must be taken to determine the actual process, to which the volume change is due, which may be either the original chemical reaction or the colloidal changes, which the reaction products undergo during the ageing of the system.

If sodium silicate solution is mixed with hydrochloric acid, molecular silicic acid is formed together with sodium chloride. This ionic

<sup>23</sup> J. Errera, *J. Chimie physique*, 1932, **29**, 577.

<sup>24</sup> Kraemer and Dexter, *J. Physic. Chem.*, 1927, **31**, 764.

reaction has a high velocity, so that it has reached completion before measurements in the dilatometer can be made. Every observation after admixture of the original compounds is connected with changes of the silicic acid. We know from the investigations of Willstätter that the originally formed compounds, mono-silicic acid and di-silicic acid undergo polymerisation, for instance

In this way high molecular silicic acids, and in the end colloidal particles, are formed to which we may attribute a configuration of the following kind (E. K. Rideal <sup>25</sup>):

Every step of this polymerisation is accompanied by a liberation of water molecules. So the very large volume increase observed in the first hours of the reaction until gel formation occurs (0.8 c.c. per 100 g.  $\text{SiO}_2$ ) can be easily understood. It is, however, significant, that after the sol has set to a stiff gel, the volume increase still continues and even 5 months after the gel formation there is no sign of its reaching a limit. The volume increase which occurs after the gel formation is about 1 c.c. per 100 g. silicium dioxide, that is to say, it is more than ten times as large as the whole volume change in the methyl cellulose system. A continuous volume increase of this magnitude has most likely to be explained by the assumption that dehydration reactions are going on in the colloidal particles (R. Schwarz <sup>26</sup>) and perhaps between the colloidal particles, whereby water molecules are liberated. In this way a network of primary chemical bonds may be established, which may perhaps go through the whole gel; there is, however, no direct experimental proof for this assumption.

A decrease in hydration in regard to water molecules bound by secondary forces may at the same time take place, since more and more hydroxyl groups, the centres of attraction for the water dipoles disappear.

The assumption of a network of primary chemical bonds between the particles in silicic acid gels may explain the high mechanical strength of these gels and the non-existence of thixotropy, as has already been pointed out by Freundlich.<sup>27</sup> It explains perhaps, too, why such gels, if dried, do not shrink indefinitely with progressive dehydration, but maintain their volume after a certain stage of drying has been reached.

The processes which take place during the maturing of viscose solutions, leading eventually to the formation of a gel, are much more complicated. It is not the purpose of this paper to discuss these processes

<sup>25</sup> E. K. Rideal, *Trans. Faraday Soc.*, 1936, **32**, 3.

<sup>26</sup> R. Schwarz, O. Liede and F. Stoewener, *Ber.*, 1920, **53**, 1509; *Koll. Beih.*, 1924, **29**, 171.

<sup>27</sup> H. Freundlich, *Thixotropy*, (*Actualités Scientifiques et Industrielles; The Colloidal State*, I.), p. 47, 1935.

in detail and, therefore, only some points are mentioned. The fresh solutions contain most probably a cellulose xanthogenate, which undergoes hydrolysis, whereby NaOH and  $\text{CS}_2$  are produced and cellulose is regenerated. Whilst the process of maturing proceeds, the sol becomes more and more hydrophobic (R. O. Herzog and R. Gaebel,<sup>28</sup> H. Bungenberg de Jong<sup>21</sup>), the quantities of ammonium chloride required for precipitation becoming gradually smaller. The viscosity, investigated at constant temperature decreases at the beginning and only increases after a time (T. Mukoyama,<sup>29</sup> E. Berl and J. Bitter,<sup>30</sup> E. Heuser and M. Schuster,<sup>31</sup> K. Atsuki<sup>32</sup>). In this respect this system is similar to the system methyl cellulose-water. Mukoyama has assumed that the minimum in the viscosity curve is due to two processes (1) a decrease in hydration of the cellulose particles, which causes a decrease and (2) the succeeding gel formation which causes an increase in viscosity. It is understandable that a decrease in hydration occurs with increasing hydrolysis, since the cellulose particles are deprived of their hydrophilic xanthogenate groups. The volume curve of the ageing of viscose solution shows a minimum too, as has been shown in Section II. The first decrease is most probably due to the hydrolytic decomposition of the xanthogenate, whereby strongly hydrated ions, such as  $\text{OH}^-$  and  $\text{Na}^+$  are formed. The increase in volume, which is observed later, is most probably the result of the progressive dehydration of the cellulose particles during the gel formation and during syneresis.

### Summary.

(1) The volume changes, which occur during the sol-gel transformations of iron hydroxide, gelatin and methyl cellulose have been measured with a sensitive mercury dilatometer; the limit of its accuracy being 0.0002 % of the total volume.

(2) In the case of methyl cellulose the volume increases during the gel formation, in the case of gelatin the volume decreases. The effect is independent of the  $p_{\text{H}}$ . The magnitude of this volume change is only a few per cent. of the volume changes, which are observed when gelatin or methyl cellulose are dissolved in water. No volume change occurs during the thixotropic sol-gel transformation of iron hydroxide.

(3) A discussion of the possible causes of the volume changes leads to the assumption that a change in hydration of the colloidal particles is responsible for it. Thus the sol-gel transformation of methyl cellulose is accompanied by a decrease, the sol-gel transformation of gelatin by an increase in hydration, whereas in the system iron hydroxide-water no change in hydration occurs. The change in hydration of gelatin and methylcellulose during the gel formation is, however, only a small percentage of the total hydration.

(4) The formation of silicic acid gels from mixtures of sodium silicate and hydrochloric acid was also investigated by means of a dilatometer. The volume increases considerably, its total change being 10 to 20 times larger than in the previously mentioned systems. After the formation of the gel there is a further increase in volume which continues for many months. It is suggested that a chemical dehydration as a consequence of continual polymerisation processes may be the reason for these large

volume changes and that these processes progress even after the gel formation.

(5) The maturing of viscose solutions, which involves the formation of a gel that undergoes syneresis, has been investigated dilatometrically and the processes accompanying these changes are briefly discussed.

I am greatly indebted to Professor F. G. Donnan, C.B.E., F.R.S., and to Professor H. Freundlich for their interest and for valuable discussions.

## STUDIES IN CHEMISORPTION ON CHARCOAL. PART VII. THE ADSORPTION OF WATER VAPOUR.

BY C. G. LAWSON.

*Received 11th November, 1935.*

In a previous publication<sup>1</sup> the effect of activation of charcoal on its adsorption of water vapour in the presence of air was studied. Charcoal activated at low temperatures was found to be far more hygroscopic than that activated at high temperatures. This was correlated with the presence of surface oxides on the charcoal, that which is stable below about 550° C. being acidic<sup>2</sup> in nature and that stable at higher temperatures being basic and far less hygroscopic. There is no evidence for a sharp transition from one oxide to the other, Rhead and Wheeler<sup>3</sup> having shown that the quantity of chemisorbed oxygen varies in a continuous manner with temperature, there being evidence of extra stability between 350° C. and 500° C., which may correspond with the acid surface oxide. A study of the  $p_H$  values of charcoal suspensions<sup>4</sup> shows a gradual change from acidity of charcoal which has been activated at low temperatures to maximum alkalinity at an activation temperature of about 850° C.

On standing in air, a charcoal which had been activated at a high temperature adsorbed more water than before.<sup>1</sup> This is probably due to the reversion of the high-temperature surface oxide to that stable at low temperatures. The  $p_H$  values of suspensions show a similar effect.<sup>4</sup> As a result of this process, the establishment of true adsorption equilibrium is not possible in the presence of air. On plotting curves of the amount of adsorption against time (or better, of the logarithms of these quantities), the process was found to consist of two parts. There was first a rapid increase in the amount adsorbed, then a very slow increase lasting for at least six months. If the charcoal had stood in air for some months before the measurements were started, then this break

<sup>1</sup> A. King and C. G. Lawson, *Trans. Faraday Soc.*, 1934, 30, 1094.

<sup>2</sup> I. M. Kolthoff, *J. Amer. Chem. Soc.*, 1932, 54, 4473.

<sup>3</sup> T. Rhead and R. Wheeler, *J. Chem. Soc.*, 1912, 831 and 846.

<sup>4</sup> A. King, *J. Chem. Soc.*, 1935, 889.

in the amount of adsorption did not occur. It is therefore due to the building up of surface oxide, rather than to its displacement by water vapour. This effect is particularly marked at low humidities (about 50 per cent. R.H.).

Another drawback to working in the presence of air is the long time required for even approximate equilibrium. This time is some days, or even weeks. It was therefore decided to repeat and extend the earlier work, using a vacuum method. In order to increase the rate of establishment of equilibrium still further, a temperature of  $80^{\circ}\text{C}$ .

was employed, since Coolidge<sup>5</sup> has shown that equilibrium is not attained readily at low pressures at low temperatures.

FIG. 1.

### Experimental.

The preparation and activation of the sugar charcoal employed was the same as in previous work.<sup>1</sup> Since the charcoal to be studied is covered with surface oxide which is metastable in the absence of air or oxygen, the method used must not involve baking out at high temperatures. The evolution of small amounts of gas (oxides of carbon) from the charcoal during the determination of the adsorption isotherm must therefore be allowed for. The only satisfactory way is to work with a pump sealed on to the apparatus. As the measurements were to be carried out at  $80^{\circ}\text{C}$ ., and as glass taps, mercury cut-offs, etc., are inconvenient at such a high temperature, a sorption balance was used. An account of a machine for winding compact silica springs has already been published.<sup>6</sup> However, a sealed-up balance of the type used by McBain and co-workers<sup>7</sup> would soon have become clogged with small amounts of oxides of carbon from the slow decomposition of surface oxide on the charcoal, rendering the rate of establishment of equilibrium slow. An apparatus was therefore designed so that these traces of gas would be eliminated as soon as they were formed. As this arrangement, which allows two or more samples of charcoal to be studied simultaneously, is rather novel, it is described in some detail.

The apparatus (Fig. 1) consists essentially of a water diffusion pump, a small quantity (3 grams) of water being continuously boiled in the lagged space A, and refluxed in the condenser B, so that the specimens of adsorbent in the pans C and D on the ends of the silica springs E and F are suspended in an atmosphere of water vapour at a given pressure. Owing to the slow rate of boiling and the open construction of the apparatus, the pressure was practically uniform throughout; however, the boiling was sufficiently rapid to prevent back diffusion of air into the apparatus.

It will be noticed that the steam is not condensed at the very bottom of the 4 mm. tube B, so that air would have to diffuse along some 4 cms. of narrow tubing before reaching the space O. When the external pressure is raised, it is done very slowly so that the water in A can warm up rapidly enough for its vapour pressure always to counter-balance the external pressure.

If there were no solution of air in the water as it condensed in B, a

<sup>5</sup> A. S. Coolidge, *J. Amer. Chem. Soc.*, 1927, **49**, 708.

<sup>6</sup> A. King, C. G. Lawson, J. S. Tapp and G. H. Watson, *J. Scientific Instr.*, 1935, **12**, 249.

<sup>7</sup> J. W. McBain and A. M. Bakr, *J. Amer. Chem. Soc.*, 1926, **48**, 693.

perfect vacuum (apart from steam) would ultimately be formed round the charcoal. Actually, no doubt, a small amount of solution does occur, though the bottom of tube B behaves as a fractionating column. Since equilibrium was never apparently delayed (as compared with the rate at which it was established in an evacuated apparatus) it was thought unnecessary to sweep out the air in the apparatus with helium, which would only be dissolved to a minute extent.

The charcoal was maintained at a constant temperature in a benzene vapour jacket G, which also served to keep the water in A boiling. The bath was tested for two hours (after it had been boiling for some hours already) and showed no change on a thermometer sensitive to  $1/50^{\circ}\text{C.}$ ; a mass of copper turnings in the bottom of G supported the inner apparatus and also prevented undue bumping. The pressure in the sorption apparatus itself was buffered by a 20 litre jar of air connected to H. Owing to the rapid setting up of equilibrium, a simple manostat, which was originally used, was found to be unnecessary.

The double surface condenser was simply made by inserting two thin quill tubes K and L inside the annular space occupied by the cooling water, the inlet tube K reaching nearly to the false bottom (which consisted of a film of sealing wax supported by a thick layer of sand). The whole benzene boiling tube was inserted in a wider tube M with mercury N at the bottom. This served both as a safeguard against fire and as an air jacket.

The suspension of the springs differed from that of previous workers in that a reference rod, hanging down the centre of the spring from the same compact support (Fig. 2), enabled the distance to be measured with the microscope to be substantially reduced. As a result, an accurate micrometer-screwed instrument could be employed. Although readings were always taken, there was no relative movement of rod and spring at the support. The readings were always repeated several times, and their average was correct to  $\pm 0.01\text{ mm.}$

FIG. 2.

The glass pans employed were similar to those of Cameron.<sup>9</sup> The charcoal had to be protected from bright light as this was observed to cause slight desorption (owing to the heating of the black charcoal).

Equilibrium was usually established within 30 to 40 minutes. Where the isotherm was steepest (large change in the amount of adsorption with a small change in water pressure), the time required was longest, up to about two hours. Initially, if the apparatus were originally full of air a few hours were necessary before the reading became constant. Owing to the thermally insulated nature of the charcoal in this type of apparatus, it is quite reasonable to suppose that the controlling factor in the establishment of equilibrium is the rate of dissipation of the heat of adsorption.

### The Adsorption of Water by Charcoal.

The isotherms obtained with various charcoals are plotted in Figs. 3 and 4 on the same scale. The results are similar in character to those obtained in the presence of air, adsorption setting in at much lower pressures in the case of charcoals covered with the acidic oxide ( $\text{C: } 400^{\circ}$ ) than with the basic oxide ( $\text{C: } 850^{\circ}$ ), although the total adsorption at high humidities is far larger in the latter case. Thus  $\text{C: } 1300^{\circ}$  finally took up over half its weight of water, yet at 50 per cent. R.H. it had adsorbed less than a totally unactivated charcoal and far less than a charcoal activated at a lower temperature. In view of the results of Langmuir<sup>8</sup> who showed

<sup>8</sup> A. E. Cameron, *J. Amer. Chem. Soc.*, 1931, **53**, 2646.

<sup>9</sup> I. Langmuir, *J. Amer. Chem. Soc.*, 1915, **37**, 1154.

that graphite retains a surface oxide up to  $1900^{\circ}\text{C}.$ , this high-temperature charcoal is almost certainly covered with oxide, which must therefore be far less hygroscopic than charcoal itself, which has been studied by McBain, Porter and Sessions.<sup>10</sup> The low-temperature acidic oxide is about equally hygroscopic as clean charcoal.

In the case of two charcoals, observations were extended so as to include a desorption curve. The hysteresis appears to be due to a variation in the nature of the surface oxide owing to its slow displacement by water. This is in accord with the work of Allmand and his collaborators.<sup>11</sup>

### Chemisorption of Water.

Several workers have noticed that on desorption of water from charcoal a small amount is irreversibly retained. Rakowsky<sup>12</sup> estimates that sugar charcoal retains 2 per cent. of its adsorbed water, some of which is not expelled on heating to redness in a current of nitrogen. Allmand,<sup>13</sup> working with

FIG. 3.—The adsorption isotherms of water on pure charcoals activated at  $400^{\circ}$ ,  $850^{\circ}$  and  $1300^{\circ}$ .

wood charcoals, found that considerable and variable amounts of water were retained *in vacuo* at room temperature and that some is not desorbed even after evacuation at red heat.

The influence of such water on the properties of charcoals might be very great, so a simple experiment was carried out to measure its extent in the case of a wood charcoal and of an ash-free sugar charcoal.

The sorption balance method is insufficiently sensitive to throw any light on the question of chemisorption of water. An apparatus was therefore constructed, consisting of a 2 mm. quill tube containing 50 mgs. of water separated by a

diaphragm from a short wide charcoal tube. The water was outgassed and sealed up: its volume was measured by a travelling microscope, to 0.2 cu. mm. The charcoal was heated to 1300° in a crucible for a few minutes and placed in the apparatus while still warm. It was then reheated to 700° C. and sealed off whilst still red hot. The diaphragm was broken by a glass rod previously introduced into the apparatus, and the water was distilled on to the charcoal. The whole apparatus was heated to 100° C. for 2 hours and left overnight at room temperature. The water was then condensed out with solid CO<sub>2</sub> and the charcoal heated to 250° C. The end of the quill tube with the water was sealed off and the volume of water remeasured. The tip of the quill tube left after sealing was cooled for two hours in liquid air, but no more water condensed therein.

Sugar charcoal gave no measurable chemisorption (less than one part in a thousand) whilst birchwood charcoal retained 0.2 per cent. of its weight of water. The chemisorbed water thus seems to be attributable to the ash of the charcoal. In this respect it resembles the peroxide which can be extracted from commercial, but not from ash-free, charcoals by dilute mineral acids, after exposing them to air and water.<sup>14</sup>

### The Adsorption of Water by Graphite.

There are, in general, three types of adsorption isotherm. Firstly, most of the adsorption may occur at low pressures; this is usual with charcoal. The second type, usual with glass, finely divided inert precipitates, etc., shows most adsorption at high relative humidities; this is usually due to capillary condensation. The third type is that of water on charcoal, which we have just considered. Frequently, two of these types are superimposed, as with sorption of water by textiles.

In order to determine which type of adsorption is occurring it is only necessary to determine three points on an isotherm. One point gives the scale of the curve; another at, say, 10 per cent. relative humidity shows whether or not the first type is present. Finally a further point at, say, 60 per cent. R.H. shows whether there is appreciable adsorption apart from capillary condensation.

Fifty grams of graphite - a commercial sample containing 1 per cent. of ash - in a wide vertical tube were evacuated via a three-way tap at about 10<sup>-4</sup> mm. for two hours, the graphite being heated to 400° C. for the last half-hour (owing to a tendency of the flakes to stick together, much "boiling" occurred during this evacuation). The three-way tap was then turned and some water in the other limb was outgassed by repeated freezing and pumping. Finally, when the vacuum became hard (in the presence of a liquid air trap), the pump was turned off and the volume of water measured with a travelling microscope.

The graphite was surrounded with a Dewar flask of water at room temperature. The narrow tube containing the water was surrounded by melting ice in another Dewar. The two were then connected by the three-way tap and allowed to stand for twenty-four hours. The tap was turned off and all the water in the narrow tube driven to the bottom, where it was measured. The melting ice was replaced by cooled water at various temperatures; the Dewars always prevented a change in relative humidity of greater than 1 per cent. per hour. Since the remainder of the glass tubing was at room temperature, any condensation here was negligible.

Relative Humidity, per cent.	.	0	28	54	74	26
Adsorption $\pi/m \times 100$	.	0	0.002	0.024	0.045	0.003

<sup>14</sup> A. King and C. G. Lawson, *Kolloid Z.*, 1934, **69**, 29.

There is too much adsorption at 54 per cent. R.H. to be explained by capillary condensation, unless the capillaries approach molecular dimensions. We must therefore either reject this hypothesis, or else assume that there is some mechanism by which a large number of capillaries of the required size is produced in graphite crystals.

It is more plausible to suppose that the same mechanism exists as for adsorption by charcoal itself,<sup>1</sup> but that the extent of the graphite surface is far smaller.

### Summary.

1. A sorption balance has been designed to measure adsorption isotherms of water on charcoal covered with various surface oxides, small quantities of desorbed gases being continuously removed.

2. Adsorption isotherms have been measured for a series of charcoals activated at different temperatures. The mean time of sojourn of water molecules on the surface of charcoal is increased by the presence of the surface oxide formed at about 400° C., and decreased by the surface oxide formed at high temperatures.

3. The extent of hysteresis is measured in the case of two charcoals.

4. When ash is present in a charcoal there may be chemisorption of water; this is not noticed with ash-free charcoal.

5. The adsorption of water on graphite is found to be of the same general type as on charcoal; the hypothesis of capillary condensation does not give a simple explanation of this fact.

In conclusion, I wish to thank the Board of Education for a grant and Mr. A. King for his interest in, and helpful criticisms of, this work.

## THE ADSORPTION ISOTHERM OF HEAVY WATER ON CHARCOAL.

BY A. KING AND C. G. LAWSON.

*Received 11th November, 1935.*

In a previous paper,<sup>1</sup> the fractionation of heavy water by selective adsorption on charcoal and silica gel was described. It was found that on progressive desorption of water from charcoal, the proportion of heavy water became greater until the final fraction contained about 1.4 times the amount of D<sub>2</sub>O in the original water. Differences in the mutual polarisabilities of the two molecular species, leading to different rates of desorption, were suggested as a reason for this. In an attempt to test this hypothesis, the adsorption isotherm for pure heavy water on charcoal previously baked out *in vacuo* has now been measured, as well as a comparison isotherm for normal water under the same conditions.

The adsorptions were carried out at 110°; the rate of establishment of equilibrium was variable and never exceeded forty minutes, while twenty

<sup>1</sup> A. King, F. W. James, C. G. Lawson and H. V. A. Briscoe, *J. Chem. Soc.*, 1935, 1545.

minutes was adequate in some cases. This limit is probably set by the time required for thermal equilibrium which will vary very much with the method used. As in our previous work with water,<sup>2</sup> equilibrium is but slowly attained where the curve is steep. The isotherms are plotted in Figs. 1 and 2, while a comparison of the adsorption portions is shown in Fig. 3. The vapour pressure curve from which the relative humidities are calculated is that of Lewis and McDonald.<sup>3</sup> Loss of water vapour as well as the possibility of interchange with the normal water from the air has to be avoided, and so the apparatus used for the measurement of the isotherms of water on charcoal had to be abandoned and a sealed up sorption balance used instead. Since several days elapsed before the readings were complete, there was, no doubt, a slight evolution of oxides of carbon from the charcoal or a slight reaction between it and the water, which McBain<sup>4</sup> has shown to occur even at room temperature. Thus,

FIG. 1.—The adsorption isotherm of heavy water on outgassed charcoal at 110°.

FIG. 2.—The adsorption isotherm of water on charcoal at 110°.

○ adsorption curve. × desorption curve.

extreme sensitivity of the isotherm, especially at the critical point where the adsorption increases greatly with a small increase in humidity, no

although the internal pressure after sealing the tube off from the pump was about  $10^{-6}$  mm., it is quite likely that this had risen to  $10^{-3}$  mm. by the time the final readings were made. In our opinion this is the reason for hysteresis which is seen to occur to a small extent, and may also account for the long equilibrium time for the steep parts of the curve.

The diagrams show that the isotherms are very similar for light and for heavy water. In view of the uncertainty of obtaining reproducible charcoal surfaces in spite of the fact that every effort was made to do so, and of the

<sup>1</sup> C. G. Lawson, *Trans. Faraday Soc.*, 1936, p. 477.

<sup>2</sup> G. N. Lewis and R. T. McDonald, *J. Amer. Chem. Soc.*, 1933, **55**, 3057.

<sup>3</sup> J. W. McBain, J. L. Porter and R. F. Sessions, *J. Amer. Chem. Soc.*, 1933, **55**, 2294.

special theoretical significance can be given to the small differences between the isotherms.

In the early work on the fractional desorption of heavy water from charcoal, there was one case where some relatively heavy water appeared to be chemisorbed; the charcoal used was a commercial sample. Our

FIG. 3.—Adsorption isotherms of heavy and light water.

× light water.      ○ heavy water.

more recent work has shown<sup>8</sup> that chemisorption does not take place on a pure charcoal at low temperatures, and in commercial charcoal is associated with inorganic impurities. However, as commercial charcoals still contain a considerable amount of combined hydrogen, there is a possibility of this tending to become heavier owing to interchange between deuterium in the water and hydrogen in the charcoal. Some freshly prepared sugar charcoal which had *not* been freed from hydrogen by chlorine treatment was therefore left in heavy water for an hour at 100° C.

and then for a week at room temperature, in a sealed up, evacuated system. The water had originally been separated from the charcoal by a diaphragm and its melting-point accurately determined. After a week the water was condensed out and sealed off from the heated charcoal. Its redetermined melting-point was within 1/100° C. of the initial value, showing that if any interchange had taken place it was small, corresponding to less than 1/10,000th of the mass of charcoal.

### Experimental.

Owing to the variations in the adsorption isotherm for light water on charcoal with relatively small variations in other factors, it is obviously desirable to study that of heavy water under identical conditions. The vacuum technique was therefore kept as simple as possible and was consequently not as rigorous as it might have been. A stock charcoal, activated at 400°, was used, and was not given the customary heating to a high temperature before weighing out as such heating could not be accurately reproduced. The charcoal, contained in its apparatus, was evacuated slowly and steadily to prevent "boiling," through a three-way tap, and when the vacuum had become hard was baked out for eighteen hours at 400°. By the other limb of the tap some out-gassed water was now distilled on to the charcoal, which was allowed to stand in this condition for two days during which time it was twice heated for an hour at 130°. The water was then pumped out and the temperature again raised to 400° for eighteen hours at less than 10<sup>-6</sup> mm. pressure. No attempt was made to heat the charcoal for a limited time at a higher temperature as this led to irreproducible results. This procedure was strictly adhered to in both cases. Water (or heavy water) was then distilled into

<sup>8</sup> See p. 477.

the apparatus, being condensed with solid  $\text{CO}_2$  and sealed off *in vacuo* after baking the constriction. No claim is made that the surfaces of the charcoal were free from surface oxide, but the preliminary water treatment should have removed the main bulk of such oxide. The isotherms are therefore not to be compared with those of McBain<sup>4</sup> who probably eliminated all traces of oxide, but rather with those of Coolidge<sup>5</sup> who used a technique comparable with ours.

The apparatus (Fig. 4) consists essentially of a silica spring balance<sup>7</sup> (A) kept at constant temperature and connected to a water reservoir (B) in a second thermostat at another temperature. Ebulliostatic methods were used to maintain a temperature constant to  $1/50^\circ$  in a small space. The whole apparatus was contained in a tube (C) at  $110^\circ$ , boiling toluene at atmospheric pressure being used to maintain the temperature of the charcoal and also used to boil benzene or toluene at reduced pressure in the second thermostat (D) around the water reservoir. The same condenser (E) served for both the liquids. Owing to the compact nature of the springs, quite narrow tubing was employed, allowing room for double vapour jackets

The pressure of the upper boiling liquid was buffered by a 20 litre jar of air, connected to an accurate mercury manometer. As equilibrium was quickly established at  $110^\circ$  actual manostats were unnecessary. A test showed that the temperature of the inner vapour jacket was constant within  $0.01^\circ$  for several hours, even when the temperature of the outer bath was varied between  $4^\circ$  and  $20^\circ$  above the boiling-point of the upper boiling liquid, and the flow of water in the condenser was altered within wide limits.

FIG. 4.

## THE RATES OF INTERACTION OF PROTO- AND DEUTERO- HYDROGEN AND METHANE WITH CHARCOAL.

BY RICHARD M. BARRER, PH.D., M.Sc.

*Communicated by ERIC K. RIDEAL.*

*Received 1st November, 1935.*

In a recent communication from this laboratory,<sup>1</sup> a study of the interactions of methane and hydrogen with carbon showed that with either gas an atmosphere of hydrogen resulted, and that a two-dimensional surface hydride of carbon was formed. Only at higher temperatures and pressures of hydrogen could any synthesis of methane be

<sup>1</sup> Barrer and Rideal, *P.R.S.*, 1935, 231; Barrer, *P.R.S.*, 1935, 253.

detected, and this synthesis was extremely slow. The adsorption was very energetic, isotherms at different temperatures indicating a heat of about 50 Cals. for the chemisorption of hydrogen, while the energy of activation on one sample showed a variation with the degree of saturation of surface of from 10 to 30 K. Cals. from 0 to 20 per cent. saturation. Both reactions are suited to the study of the relative velocities of reaction of proto- and deuterio-molecules. Three sources of differing reaction rate may be anticipated, due to mass variation, zero-point energy differences, and different permeabilities towards energy barriers.

The first effect will not be large with  $\text{CH}_4$  and  $\text{CD}_4$  molecules, since  $\sqrt{\frac{M_{\text{CD}_4}}{M_{\text{CH}_4}}} = 1.12$ . Both the reactions involve proton exchange, which can include permeability effects.

### Experimental.

The apparatus used in the chemisorption of hydrogen and methane has been described elsewhere (ref. 1). Deuterium was prepared in the

PREPARATION OF DEUTERIUM

FIG. 1.

apparatus of Fig. 1. A little heavy water vapour was admitted to a tungsten filament (thoroughly out-gassed at 2300° K. for several hours) and the filament was then burned at red heat in the water vapour, so that deuterium was liberated. The resultant gases were then passed through a U-tube immersed in liquid air, and were allowed to diffuse through a palladium tube heated to 700° K. The effluent gas was collected and stored by means of a Toepler pump. Methane and deuterio-methane were prepared from light and heavy water and aluminium carbide, and the velocity sorption checked against pure methane from another source to test its purity.

## Results.

## (a) The Activated Sorption of Hydrogen and Deuterium.

The activated adsorption rates of the hydrogens were studied over as wide a temperature interval as possible (500°-900° K.) on a sugar carbon of 0.01 per cent. ash content. Pressure-Time curves gave the retardation in sorption velocity already observed (Barrer<sup>1</sup>), even at low concentrations of hydrogen. Sorption rates were compared by commencing experiments with equal samples of each gas, and drawing tangents to  $\text{Log}_{10}$  (Pressure)-time curves at points of equal adsorption. Typical results are given in Table I. In all the experiments 4.1 grammes of carbon were used, and check experiments made to show that no change in the adsorbent had taken place.

65.2 (when sorption complete.)					

Although the value of  $\frac{\partial}{\partial t} \log (p_i - p_s)$  decreases continuously the ratio of the expression for hydrogen and deuterium remains constant for stages where equal amounts of gas are adsorbed. The deuterium samples employed were 80-60 per cent. pure, since an 80 per cent. heavy water was employed in their preparation. As reaction proceeded isotopic fractionation by reaction occurred, and over the later stages of the reaction substantially pure deuterium was being chemisorbed. Thus the ratio of the rates became constant over the final stages of chemisorption, and only the ratios in this reaction region were employed in subsequent calculations. Table I. shows a quite large difference the reaction in velocities at a given temperature. Table II. shows how the ratio of reaction velocities varied as a function of temperature.

TABLE II.

Temperature °K.	890	698	603	585	500
Ratio of velocities.	1.44	1.77	1.84	1.94	2.37

As the temperature decreased the ratio increased. This is in accordance with differences in rate of reaction due to zero point energies, but not in accord with differences caused by effusion processes. At the same time the possibility of both these processes occurring simultaneously has to be considered. A conclusion on this point may be arrived at as follows. Reaction proceeds at any instant according to an expression

$$-\frac{dp}{dt} = k(p_i - p_s)e^{\frac{E}{RT}} \quad . \quad . \quad . \quad (1)$$

so that  $-\frac{d \ln(p_i - p_e)}{dt} = K e^{-\frac{E}{RT}} = k_i$  at constant temperature. For the reaction involving the hydrogen isotopes we may write

$$r = \frac{K_{H_2}}{K_{D_2}} = e^{-\frac{(E_{H_2} - E_{D_2})}{RT}} = \frac{\frac{d}{dt} \cdot \{\ln(p_{H_2} - p_{e_{H_2}})\}}{\frac{d}{dt} \cdot \{\ln(p_{D_2} - p_{e_{D_2}})\}} \quad (2)$$

as given for example in Table I.

Hence 
$$\frac{\partial}{\partial \frac{1}{T}} \cdot \log r = -\frac{(E_{H_2} - E_{D_2})}{2.303R} = -\frac{\Delta E}{2.303R} \quad (3)$$

Equation (3) is a general differential equation which will give a family of particular solutions of which two cases may apply:

$$2.303 \log r = -\frac{\Delta E}{RT} \text{ (without effusion)} \quad (4)$$

and

$$2.303 \{\log r - \log \sqrt{2}\} = -\frac{\Delta E}{RT} \text{ (with effusion)} \quad (5)$$

The general equation (3) was first used to determine  $\Delta E$  by plotting  $\log r$  as a function of  $1/T$ . The value thus obtained was 780 Cals. Now in Table III. are given the values of  $\Delta E$  calculated from equations (4) and (5) respectively:—

TABLE III.

Temp. °K.	Ratio (Equation 4).	$\Delta E$ Cals.	Ratio 1.414 (Equation 5.)	$\Delta E$ Cals.
890	1.44	650	1.02	33
898	1.77	800	1.25	315
903	1.84	740	1.30	310
955	1.94	800	1.37	310
900	2.37	865	1.68	706
		Average 700		

Obviously equation (5) disagrees with equation (3), nor does it give constant  $\Delta E$  values, where-

TABLE IV.

Amount Sorbed c.c. at N.T.P. $\times 10^3$ .	Velocity Constant at 696° K.	Velocity Constant at 603° K.	Apparent Energy of Activation, cals./gram. mol.
30.0	0.186	0.0342	15,700
44.0	0.138	0.0194	17,900
53.5	0.117	0.0137	18,700

as there is good agreement between (4) and (3). Thus diffusion in the bulk phase or on the surface does not combine with the chemical process as a rate determining step in the temperature range studied. The molecules of hydrogen and deuterium react according to the scheme:

and there is a preliminary van der Waals adsorption sufficiently rapidly established to maintain the surface concentration at its equilibrium value.

The apparent energy of activation for the chemisorption of hydrogen on charcoal F is shown in the following data to be initially about 15,000 cal./gram. mol., and to increase steadily as the amount of gas sorbed increases.

TABLE V.

Temperature °K.	$K_{CH_4}$	$K_{CD_4}$	Ratio.
83S	—	0.044	—

	0.381	—	—

The sorption data for methane were treated in a similar manner to those for hydrogen. The results are given in Table V.

From Table V. one can calculate the zero-point energy differences needed to explain the different reaction rates:—

Temperature °K.	83S	920	950
Zero point energy difference (calories)	880	770	700

The apparent energy of activation<sup>2</sup> for the chemisorption of methane on carbon F is given by the data here shown.

Temp. °K.	Velocity Ratio $\frac{CH_4}{CD_4}$	Energy K Cals.
838-950	4.44 —	26.7
838-950	— 5.22	31.4

### Discussion.

It is of importance to note that  $\Delta E$  remains constant down to 500° K. At this temperature, according to some recent work,<sup>3</sup> one would expect that effects due to tunnelling would intervene. This would

<sup>2</sup> This energy is so much lower than the value *ca* 53 K. Cals. observed on another charcoal, C. (ref. 1) as to suggest that the gas prepared from carbide and employed in these chemisorptions might not be methane but hydrogen. Consideration of the actual velocity constants for chemisorption of hydrogen and of methane on the two carbons C and F gave the following relationship:

$$\begin{aligned} \frac{A_{H_2} - \text{Carbon C}}{A_{H_2} - \text{Carbon F}} &\sim \frac{1}{4} \\ \frac{A_{CH_4} - \text{Carbon C}}{A_{CH_4} - \text{Carbon F}} &\sim \frac{1}{100} \end{aligned}$$

The velocities and energies of activation of hydrogen sorption on both carbons were comparable, but there seems something specific in the increase in  $K$  and decrease in  $E$  for carbon F. To show that the gases employed were methanes, a comparison was made of the sorption rates of the gas from aluminium carbide, hydrogen, and pure methane from another source. The results are as shown.

<sup>3</sup> Bell, *P.R.S.*, 1933, 139A, 466; Bawn and Ogden, *Trans. Faraday Soc.*, 1934, 30, 432.

Temp. °K.	$K$ (Hydrogen.)	$K$ (Gas from Carbide.)	$K$ (Methane).

	—	—	0.300
	—	0.380	—
860	0.502	—	0.330
	—	0.096	—
	0.532	—	—

cause an apparent increase in  $\Delta E$  which is not realised in the experiment. One thus finds that quantum mechanical effects of the type indicated are absent in a reaction which should be very favourable to their occurrence. The magnitude of  $\Delta E$  is that encountered in other heterogeneous processes, such as the diffusion of hydrogen through palladium<sup>4</sup> (830 Cals.) or the hydrogenation of ethylene by nickel<sup>5</sup> (700 Cals.).

### Summary.

(1) The relative rates of sorption of proto- and deuterio-molecules of hydrogen and methane on carbon indicate zero-point energy differences of 770 and 750 Cals. respectively.

(2) The hydrogen sorption showed no tunnelling mechanism down to 500° K., and no mass factor in the constant A of the equation

$$\frac{(\text{rate})_{\text{H}_2}}{(\text{rate})_{\text{D}_2}} = Ae^{-\frac{\Delta E}{RT}} \text{ so that } A \approx 1.$$

The ratio of the velocities decreased in both sorptions as the temperature increased.

I wish to thank Professor E. K. Rideal, F.R.S., for his continued interest in the work, and the 1851 Commissioners for an Overseas Scholarship.

## THE INTERACTION OF LIGHT AND HEAVY WATER WITH ALUMINIUM CARBIDE AND CALCIUM PHOSPHIDE.

BY RICHARD M. BARRER, Ph.D., M.Sc.

*Communicated by ERIC K. RIDEAL.*

*Received 1st November, 1935.*

In a paper on the chemisorption of light and heavy hydrogens and methanes by carbon<sup>1</sup> it was shown that the differences in rate of sorption had all the properties of differences due to zero point energies. The differences, when expressed as,

$$\frac{k_{\text{H}_2}}{k_{\text{H}_1}} = Ae^{-\frac{\Delta E}{RT}},$$

gave a value of  $A = 1$ .

$\Delta E$  was constant between 500° and 900° K., and no penetration of energy barriers could be detected. If reactions could be studied which

<sup>1</sup> Barrer. This volume, p. 481.

proceed at room temperatures, an enhanced separation in the velocity constants might occur, and would imply quantum mechanical effects of the type discussed among others by Bell<sup>2</sup> and Bawn and Ogden.<sup>3</sup>

Many measurements of heterogeneous processes have shown that a  $\Delta E$  due to zero point energy differences may be set at 600-900 Cals., with considerable certainty, but a value of  $\Delta E$ , as calculated from the above equation of about 2000 Cals. would at low temperatures imply tunnelling through energy barriers. A test of this could be made by observing  $\frac{\partial(\Delta E)}{\partial T}$  which should decrease rapidly with increasing temperature

until a constant value of  $\Delta E$ , due to zero point energy difference only, was observed.

Reactions which proceed readily at room temperatures are the decomposition with water of aluminium carbide and of calcium phosphide with liberation of methane and of phosphine respectively. It has been stated<sup>4</sup> that at 80° C. the ratio  $\frac{k(\text{H}_2\text{O}-\text{Al}_4\text{C}_3)}{k(\text{D}_2\text{O}-\text{Al}_4\text{C}_3)}$  was 23, a value suggesting a tunnelling process. Another method which did not, however, eliminate the possibility of exchange reactions, gave a separation factor of only two.<sup>5</sup>

### Experimental.

The apparatus employed in the decomposition of carbide and phosphide is shown in Fig. 1.

By manipulation of the two-way tap the light or heavy water (98 per cent. D content) could be distilled on to the carbide or phosphide. These had both been heated and thoroughly out-gassed under high vacuum, and during the distillation were immersed in liquid air. When the temperature was brought to room temperature reaction proceeded and the velocities were

APPARATUS FOR DECOMPOSITION

reaction no appreciable decreases in the weight of either occurred. Under these conditions a zero order process was obtained. When an experiment was completed the light or heavy water was again brought back to the

show that the carbide or phosphide was of unchanged reactivity. The reaction with calcium phosphide was so vigorous that water vapour only could be used in the reaction. The two-way tap was opened and water vapour allowed to enter the evacuated system containing phosphide. This vapour then decomposed the phosphide.

The phosphide used was a commercial sample. The carbide was made by heating aluminium powder and carbon in an electric furnace *in vacuo* (thereby avoiding contamination by aluminium nitride).

### Results.

The reaction

was studied between 273° and 293° K. A large number of experiments were made with light water to determine the temperature coefficient of the reaction. A sequence of these experiments is given in Table I.

TABLE III.

tubes  $\text{H}_2\text{O}$  or  $\text{D}_2\text{O}$  with liquid air. The method allowed the same samples of carbide and phosphide to be used with both heavy water and light water, without destroying either. This avoided the variability encountered with different samples even of the same batch. Control experiments were made throughout to

TABLE II.

Temperature Range.	Temperature Coefficient.	Apparent Energy of Activation. (Cals. mol.).
273-287	3.90	15,200
273-288.6	4.15	14,200
273-292.2	5.45	13,900
273-291.7	4.85	13,500
		Average 14,200

Similar series of experiments were conducted between 273 and 288.6, 292.2, 291.7° K., and in Table II. are collected the temperature coefficients and an apparent energy of activation calculated therefrom.

The particular point of interest is the possibility of repeating the large separation in reaction velocity (23 : 1 at 353° K.) reported by Urey and Price.<sup>4</sup> Since the same sample of carbide was used with both light and heavy water and control experiments performed

From Table II.  $\frac{k_{H_2O}}{k_{D_2O}} = 3.9$  at  $273^\circ \text{K}$ . We may conclude from this small ratio that no tunnelling through an energy barrier is involved, whilst the difference in zero-point energy needed to give the observed separation

is 750 Cals. Since  $\sqrt{\frac{D_2O}{H_2O}}$  is nearly unity mass differences are insignificant.

The reaction of water vapour with powdered calcium phosphide according to the equation

TABLE IV.

is limited by the rate at which diffusion can occur, and by the relative vapour pressures of light and heavy water (about 10 : 9 at room temperature <sup>6</sup>). Table IV. shows the results of a set of experiments.

It was also shown that, when the vapour pressure of the water was constant, and the temperature of the phosphide was raised, the reaction velocity did not increase more than would conform to a  $\sqrt{T}$  diffusion in the material (Table V.).

### Discussion.

The decomposition of calcium phosphide by water vapour is an example of a chemical process controlled by a non-activated

diffusion. It is impossible to control decomposition by liquid water. The much slower carbide reaction is governed by a chemical process without evidence of a superposed diffusion. In the carbide lattice are two kinds of aluminium atom plane and two kinds of carbon atom plane per lattice layer.<sup>7</sup> Thus there may be different types of aluminium-carbon bond, and one cannot assign the activation energy to any particular type. The heat of the reaction

is 352 K. Cals.<sup>8</sup> Therefore, the average energy per C—H bond formed is 28 K. Cals., compared with what may be an average energy of activation per C—H bond formed of 14 K. Cals. That no process ascribable to tunnelling of energy barriers could be observed suggest that the barriers are much wider than thought at present, or that present-day calculations do not yet include all the important factors.

<sup>8</sup> Terebesi, *Helv. Chim. Acta*, 1934, 819; Internat. Critical Tables.

### Summary.

(1) The decomposition of aluminium carbide by liquid water has an apparent energy of activation of 14 K. Cals. The reaction rates for light and heavy water are as 3.9 : 1 at 273° K., corresponding to a zero-point energy difference of 750 Cals. There is no evidence of a tunnelling mechanism at 273° K.

(2) The decomposition of calcium phosphide by water vapour is governed by a diffusion process. At constant water vapour pressure the temperature coefficient is very small. The rates of decomposition by light and heavy water vapour are in the ratio of the vapour pressures of light and heavy water.

I am indebted to Professor E. K. Rideal for discussion and encouragement, and to the 1851 Commissioners for an Overseas Scholarship.

## THE THERMAL DECOMPOSITION OF LIGHT AND HEAVY AMMONIA AND PHOSPHINE ON TUNGSTEN.

BY RICHARD M. BARRER, PH.D., M.SC.

*Communicated by ERIC K. RIDEAL.*

*Received 1st November, 1935.*

The decomposition of ammonia on tungsten filaments has been studied by various workers,<sup>1</sup> between 2 and 500 mm. pressure. The reaction has not been adequately examined at low pressures. Schwab's<sup>2</sup> work is confined mainly to the decomposition on platinum. The decomposition of phosphine on tungsten was studied by Melville and Roxburgh.<sup>3</sup> Both these reactions were re-examined, using proto- and deuterio-molecules, mainly at low pressures. The determination of zero point energy differences on a number of tungsten catalysts was not however the only reason for pursuing the investigations. There exists a wide discrepancy in recorded energies of activation for the seemingly simple zero order ammonia decomposition. These energies range from 26 to 47 K. Cals. One can conclude either that the methods of measurement are inadequate, or that the activation energy varies in a random manner from one tungsten catalyst to another. The latter consideration seems unlikely in view of the stability of a polycrystalline tungsten filament when outgassed at 2000° C. We have therefore measured the energy of activation by the compensating filament method.<sup>4</sup> This was done for both the phosphine and the ammonia reactions and trustworthy energies of activation were obtained. If a number of true energies of activation (*i.e.*, for the zero order reactions)

<sup>1</sup> Hinshelwood and Burk, *J.C.S.*, 1925, 127, 1105; Kunsman, *J.A.C.S.*, 1928, 50, 2100; Hailes, *Trans. Faraday Soc.*, 1931, 27, 601; Motschan, *Perevesen-seffy Roginsky Acta Physicochimica*, 1935, 2, 203.

can be measured, absolute rates can be calculated, just as for homogeneous processes. The well-known characteristics of polycrystalline tungsten filaments<sup>5</sup> enabled the calculations to be made for the two reactions here studied.

### Experimental.

The reactions occurred on tungsten filaments of lengths 31 and 9 cms. and of 0.1 mm. diameter. Each filament during reaction formed one arm of a Wheatstone's bridge. The bridge was kept in balance, and the catalyst so maintained at constant temperature, by increasing the total current through the bridge as the reaction proceeded. From the properties of ideal filaments,<sup>6</sup> the temperature could be calculated for a given filament current *in vacuo*. In the presence of the gas the current was increased until the resistance (and therefore temperature) of the filament was that already measured *in vacuo*. The cooling effect of the 1 mm. tungsten lead was allowed for by calculation as suggested by Langmuir, MacLane and Blodgett.<sup>7</sup> This does not yet allow the true temperature coefficient to be measured however. The velocity on the short filament at temperature  $T_1$  was next subtracted from the velocity on the long filament at  $T_1$ . The resultant velocity was taken as representing the velocity on the middle section (22 cms.) of the long filament. This resultant velocity was used to determine energies of activation.

Light and heavy ammonias and phosphines were prepared from magnesium nitride, and calcium phosphide, previously outgassed, in an apparatus described elsewhere.<sup>8</sup> The D-content of ammonia was estimated from vapour pressure measurements, and of phosphine from density measurements. 98 per cent.  $D_2O$  was used in preparing  $ND_3$  and  $PD_3$ . Ammonia and phosphine were purified by distilling several times between liquid air and solid carbon dioxide. Hydrogen was prepared electrolytically, and passed over palladium-coated copper at  $350^\circ C$ . and phosphoric oxide. Cylinder nitrogen (99 per cent. pure) was passed over palladium-coated copper at  $350^\circ C$ . and through a liquid air trap. The filaments were thoroughly outgassed (several hours at  $2000^\circ C$ .) before use, and were also outgassed between each experiment for 20 minutes at the same temperature. Under these severe conditions the catalytic activity was reasonably constant. After an experiment with ammonia a filament retained occluded gas, which with for an initial gas pressure  $10^{-2}$  cm. was comparable in amount with this pressure. The phosphine decomposition gave negligible occlusion. This suggests that the occluded gas was nitrogen. For the phosphine decomposition a stoichiometric relation held between initial and final volumes as demanded by the equation  $2PH_3 = 2P + 3H_2$ , the phosphorous being deposited as the red variety on the glass walls. The ammonia decomposition was more complicated. More gas was obtained finally than the original pressure indicated. This was traced to a strong and relatively slow sorption<sup>9</sup> by the walls of the reaction vessel. Typical of this sorption are the data here shown.

Ammonia was therefore admitted at a higher pressure than that at which the experiment was subsequently conducted, until the sorption was nearly completed. Some was then frozen out, a convenient pressure obtained, and after a further interval for desorption the run was commenced.

## Kinetics of the Reactions.

The ammonia decomposition was studied between  $6.1 \times 10^{-4}$  cms. and  $6.3 \times 10^{-3}$  cms. pressure. The reaction is nearly of zero order, except at the highest temperatures (Table I.) and lowest pressures, on the 9 cm. filaments.

Similarly at the lower temperatures (ca  $900^\circ$  K.) at which measurable

decomposition occurred on the longer 31 cm. filaments, a good approximation to zero order was again found (Fig. 1). A feature of the reaction was the occurrence of a *zero order velocity constant at  $6.1 \times 10^{-4}$  cms. pressure of only 0.37 times the velocity constant at pressures of 10 to  $60 \times 10^3$  cms.* Also decomposition occurred with an initial pressure of  $6.1 \times 10^{-4}$  cms. until  $7 \times 10^{-3}$  cms. pressure obtained in the gas phase. Both these effects

FIG. 1.

were ascribed to sorption on the walls. The walls by giving off ammonia as that in the gas phase was decomposed, acted as a reservoir of ammonia which kept the gas phase and therefore filament surface concentrations nearly constant and so gave the appearance of a zero order reaction on the filament, which could yet be less rapid than the true zero order process at greater pressures. On this basis the relation between the initial value of  $dp/dt$  and

the pressure should be that of an isotherm, of which the initial curvature is controlled by the sorption isotherm of ammonia on glass, and of which the last portion is controlled by the saturation concentration at the tungsten surface. The relevant data, collected in Table II., and Fig. 2, show that this is indeed the case :

Over a sixteen-fold increase in pressure there was a 2.5-fold increase in velocity, and then above about  $10^{-2}$  cms. the velocity remained constant.

FIG. 2.

FIG. 3

FIG. 3a.

FIG. 3b.

The kinetics of phosphine decomposition were not complicated by sorption on the walls and enabled an interesting change in the order of the reaction with varying pressure to be followed.

On a 31 cm. filament between  $10^{-4}$  and  $10^{-3}$  cms. pressure Fig. 3a shows that a first order reaction was obtained. On a 9 cm. filament at pressure

TABLE III.

61	3.07	—	61.9

(15 to 20)  $\times 10^{-3}$  cms. pressure the plot of Log (press.) against time was definitely curved, showing a reaction of intermediate order (Fig. 3b). Finally at pressures of a few millimetres a zero order reaction was found (Fig. 3c). The kinetic equation for the reaction

of intermediate order, at 860° K. was either

$$-dp/dt = k p^{\frac{1}{2}} \quad (1)$$

$$\text{or, } -dp/dt = ap/1 + bp \quad (\text{with } a = 0.0227 \text{ and } b = 26.60). \quad (2)$$

as is shown by the data of Table III. The rate equation thus follows a Freundlich or a Langmuir isotherm.

The most interesting way to follow the transition from first to zero order is by measuring the half-life period as a function of pressure. At low pressures the half-life ( $t_{\frac{1}{2}}$ ) should be independent of pressure, and at high pressures proportional to it. These predicted relations are realised in the data of Table IV.

The experiments establish that the real rate determining process is unimolecular with respect to phosphine. Fig. 4 shows the relation between the half-life period and the pressure at two different temperatures, on a 9 cm. filament.

### Energetics of the Reactions.

The velocity of thermal decomposition of ammonia on 9 and 31 cm. filaments was measured over a range of temperatures. Excellent linear graphs of Log ( $k$ ) against  $\frac{1}{T}$  ( $T = ^\circ\text{K.}$ ) were obtained. The slope for the 9 cm. filament is greater than for the 31 cm. filament, the apparent energies being respectively 52.3 and 43 K. Cals. The corresponding rate equations are:

$$\text{Log}_{10} K_1 = 7.409 - \frac{52,300}{2.303RT} \quad (1)$$

$$\text{Log}_{10} K_2 = 6.475 - \frac{43,000}{2.303RT} \quad (2)$$

From the linear graphs of  $\text{Log } K$  against  $1/T$ , the value of  $K_1 - K_2$  was obtained at two different temperatures. The integrated van't Hoff isochore

$$\text{Log}_e \frac{(K_1 - K_2)_{T_1}}{(K_1 - K_2)_{T_2}} = \frac{E}{R} \left( \frac{1}{T_1} - \frac{1}{T_2} \right)$$

then gave the true value of  $E$  for the zero order reaction as 42.400 cal./gram. mol. for 22 cms. of the central zone of the 31 cm. filament. The true rate equation is then

$$\text{Log}_{10} (K_1 - K_2) = 6.35 - \frac{42.400}{2.303RT}$$

The energy of activation for the decomposition of phosphine was calculated from the relationship between the half-life period ( $t_{1/2}$ ) and the

FIG. 4.

temperature, and also from the value of  $dp/dt$  at constant pressure and at various temperatures. The temperature coefficient was not the same at all pressures for a given rise in temperature. The relationship between derived energies of activation  $E_1$  and  $E_2$  for the reaction proceeding as a first and an apparent zero order reaction respectively is  $E_1 + \Delta H_s = E_2$ , where  $\Delta H_s$  is the heat of sorption of the phosphine on tungsten. The values of  $E$  as a function of pressure are given in Table V.

TABLE V.

9 cm. filament.

 $T_1 = 401^\circ \text{ K.}$  $T_2 = 972^\circ \text{ K.}$ 

Press. (cms. $\times 10^3$ ).	$(t_{1/2})_{T_1}/(t_{1/2})_{T_2}$	$E(\text{K. Cals.})$	$\left(\frac{dp}{dt}\right)_{T_1}/\left(\frac{dp}{dt}\right)_{T_2}$	$E(\text{K. Cals.})$
0.23	—	—	3.0	26.6
0.47	2.74	24.6	—	—
8.00	—	—	3.7	32.0
14.00	3.60	31.3	—	—
18.00	—	—	3.6	31.3
34.00	3.86	33.0	—	—
127.00	3.99	34.2	—	—

Similarly for a 31 cm. filament between 878.8° K. and 919.2° K. the following values were obtained :

<i>Press</i> (cms. 10 <sup>3</sup> ).	<i>E</i> (K. Cals).
0.41	26.5 (First Order Reactions)
9.0	31.5 (Intermediate Order)
80.0	32.5 (Approximate Zero Order)

From the differences in the extreme values of *E* of 10 and 6 K. Cals. for the 9 and 31 cm. filaments one can assume  $\Delta H_a$  to be about 8 K. Cals. The rate equations are :

$$\text{Log} \left( \frac{dp}{dt} \right)_1 = 5.69 - \frac{32,500}{2.303RT},$$

and

$$\text{Log} \left( \frac{dp}{dt} \right)_2 = 5.39 - \frac{32,500}{2.303RT},$$

for the long and the short filaments respectively. From these relations when  $\text{Log } dp/dt$  is plotted as a function of  $1/T$  the true energy of activation may be derived, since

$$\frac{\partial}{\partial T} \left[ \text{Log} \left\{ \left( \frac{dp}{dt} \right)_1 - \left( \frac{dp}{dt} \right)_2 \right\} \right] = \frac{E_{\text{true}}}{2.303R}.$$

From the values of  $dp/dt$  at 800° and 900° K., and employing the integrated isochore one obtains.

$$\text{Log} \frac{0.00273}{0.000274} = \frac{E_{\text{true}}}{2.303R} \left( \frac{1}{800} - \frac{1}{900} \right),$$

whence  $E = 32,200$  Cals.

### The Influence of Products upon the Velocity of Decomposition.

It has been shown that hydrogen has no effect upon the decomposition of phosphine.<sup>2</sup> It has been stated by Schwab<sup>3</sup> that the ammonia decomposition is retarded by the resultants, whereas Hinschelwood Burk and Hailes<sup>1</sup> consider the reaction to be unretarded, in spite of a known strong sorption of hydrogen by clean tungsten,<sup>10</sup> or of the possibility of nitriding of the filament. A new series of experiments was carried out on the influence of hydrogen, nitrogen and oxygen on the ammonia reaction. In an orienting experiment the filament was heated in ammonia at 1700° K. until the latter was decomposed. Residual hydrogen, nitrogen and ammonia were pumped off, but the filament was not outgassed, and retained occluded gases. A subsequent experiment at 984° K. gave the same velocity of decomposition as did the outgassed filament. The wire (0.1 mm diameter and 31 cms.

long) gave off 0.25 c.c. of gas at N.T.P. when it was subsequently glowd at 2200° K. Thus occluded gas has no influence. Further investigation

<sup>10</sup> Roberts, *Proc. Camb. Phil. Soc.*, 1934, 30, 1/4.

was carried out by adding various initial pressures of hydrogen and nitrogen and observing the decomposition velocities. The results of Table VI. show that these gases had no observable influence.

Oxygen on the other hand produced definite retardation. Ammonia was admitted, and the run commenced at  $975^\circ \text{K}$ ., the usual zero order reaction being obtained. The ammonia was frozen out, and the oxygen at  $2 \times 10^{-3}$  cms. pressure admitted to the filament at  $600^\circ \text{K}$ . and then pumped off. The original

experiment was then recommenced the value of  $dp/dt$  being first negligible and then increasing steadily towards the original value, apparently due to a process of clean-up of the oxygen film which restored the original catalytic surface. Finally the experiment was repeated with some gaseous oxygen present.  $dp/dt$  was now no longer positive (*i.e.*, an increase in

total pressure with time) but negative.<sup>11</sup> The results are summarised in Fig. 5. It is of interest that the effect of oxygen is not permanent at  $975^\circ \text{K}$ .

### Relative Velocities of Decomposition of Proto- and Deutero-Molecules.

Three samples of ammonia of D-contents 98 per cent., 30 per cent. and 0 per cent.

were prepared. These were decomposed on three catalysts A, B, C. The results of a number of the experiments are summarised in Tables VII., VIII., IX.

For the gases of the compositions of the Table VII., a difference in zero point energy  $\Delta E$  of 550 cal./mol. will give the observed separation. Assuming a linear relation between D-content and  $\Delta E$ , the  $\Delta E$  for pure  $\text{NH}_3$  and  $\text{ND}_3$  is 800 cal./mol.

For catalyst B,  $\Delta E \approx 790$  cal./gm. mol. for the pure gases  $\text{ND}_3$ ,  $\text{NH}_3$ .

Experiments were made on similar lines with PH<sub>3</sub> and PD<sub>3</sub>. The separations encountered were smaller. Values of  $dp/dt$  were derived from pressure-time curves, and, as for ammonia, the relation

$$\text{Log} \left( \frac{dp}{dt} \right)_{\text{PH}_3} / \left( \frac{dp}{dt} \right)_{\text{PD}_3} = \frac{\Delta E}{RT}$$

was used to calculate  $\Delta E$ . The results of numerous experiments on two different catalysts D and E are summarised in Tables X. and XI. Again both catalysts D and E gave the same separation  $\Delta E$  of 550 cal./gram. mol. for pure PH<sub>3</sub> and PD<sub>3</sub>.

### Discussion.

Since hydrogen has no influence upon the reaction rates for either phosphine or ammonia, it is improbable that the evaporation of a tungsten hydride layer is a rate determining step. Since, however, proto- and deuterio-molecules do not decompose equally fast, in both reactions rearrangement of hydrogen bonds is involved. Thus evaporation of tungsten-nitride or a tungsten-phosphorus layer is not a rate controlling step. For the phosphine decomposition our experiments establish that the rate determining step is a true first order reaction; and the same is most probably true of the ammonia decomposition.

The simplest theory supposes that the energy is communicated by the underlying solid. Then:

$$\text{Rate} = No. (p \cdot \nu) \cdot e^{-E/RT} \quad (1)$$

Where  $No.$  = the number of molecules adsorbed/cm.<sup>2</sup> and  $\nu$  has the dimensions of a frequency, and is often identified with the characteristic frequency of the solid. The factor  $p$  allows for deactivation before reaction, and for the participation of many degrees of freedom in supplying the activation energy (*cf.* Eqn. (2)). More explicitly<sup>13</sup> the equation becomes:

$$\text{Rate} = No. f(E_1, n) \frac{\alpha}{\beta} \cdot \nu \cdot e^{-E/RT} \quad (2)$$

Here  $f(E_1, n)$  expresses the effect of  $n$  degrees of freedom on the rate,  $\alpha$  is the rate at which the preactivated molecules become critically activated and decompose, supposing no deactivation occurred and  $\beta$  is the rate at which deactivation takes place.  $f(E_1, n) \geq 1$ ;  $\alpha/\beta \leq 1$ . The transition state method<sup>14</sup> gives the rate as:

$$No. \cdot C \cdot F'_a / F_n \cdot KT/h \cdot e^{-E_a/RT} \quad (3)$$

<sup>13</sup> Hinshelwood, *J.C.S.*, 1935.<sup>14</sup> Tolman "Statistical Mechanics; Chem. Cat. Co." 1927, Eyring, *J. Chem. Phys.*, 1935, 3, 107 *et al.*

$C$  is the reciprocal of the number of times the activated state must be crossed before reaction occurs.  $F'_a$  and  $F_n$  are partition functions for the activated and normal states respectively.  $F'_a$  however does not include the partition function of the co-ordinate in which decomposition occurs. The partition function of this co-ordinate is included in the factor  $KT/h \cdot e^{-E_a/RT}$ .  $T$  has the maximum rates, at the temperature  $\simeq 1000^\circ \text{K.}$ , according to (1), (2); and (3) respectively<sup>15</sup> equal to

$$5 \times 10^{12} \cdot e^{-E/RT} \quad \text{and} \quad 2 \times 10^{13} \cdot e^{-E_a/RT},$$

where the  $E$ 's are not defined in quite the same way;

$$E = E_0 + \Sigma [f \cdot (\nu' T)] - RT,$$

if  $E$  is obtained from the expression  $\partial/\partial T \cdot \log(\text{rate}) = E/RT^2$ . In what follows we shall neglect  $\Sigma [f(\nu' T)]$ . Also  $\nu$  in (2) is taken as equal to the lattice frequency of tungsten.

At saturation  $No = 7.0 \times 10^{14}$  mols./cm.<sup>2</sup> (one  $\text{PH}_3$  or  $\text{NH}_3$  molecule per two W atoms). The ratio 1.4 : 1 gives the ratio of real<sup>5</sup> to apparent surface.

The rate constants at  $1000^\circ \text{K.}$  and at  $900^\circ \text{K.}$  for the ammonia and phosphine decompositions are respectively  $1.34 \times 10^{-3}$  cms./minutes and  $2.73 \times 10^{-3}$  cms./minute. Equation (1) gives a value of  $p = 10^{-3}$  and  $1.4 \times 10^{-4}$  for the ammonia and phosphine decompositions respectively (assuming  $\nu = 5 \times 10^{12}$ ). On the basis of equation (2) this is to be interpreted as a small ratio  $\alpha/\beta$ . When  $\nu = KT/h = 2 \times 10^{13}$ , and  $E = (E_0 - RT)$ , as in the equation (3) the values of  $p = C \cdot F'_a/F_n$  become  $2 \times 10^{-4}$  and  $3 \times 10^{-5}$  for the ammonia and phosphine decompositions respectively. A restriction on the validity of these calculations is the assumption of a uniform catalytic activity of the surface.<sup>16</sup>

It is interesting to collect the energies of activation recorded for each reaction in the series (see table on opposite page).

The most uncertain method of measuring filament temperature seems to be direct determination of resistance, which often gives much lower energies than do measurements by other means.

### Summary.

1. The thermal catalytic decomposition of ammonia on tungsten filaments has been studied between  $6 \times 10^{-3}$  and  $6 \times 10^{-4}$  cms. pressure at temperatures between  $950^\circ$  and  $1150^\circ \text{K.}$  The thermal catalytic decomposition of phosphine has been studied between  $10^{-1}$  and  $2 \times 10^{-4}$  cms. pressure, and from  $800^\circ$  to  $970^\circ \text{K.}$  On various tungsten catalysts the ammonia decomposition was over early stages a zero order reaction. Towards the end of decomposition, or at the lowest pressures the velocity fell as the ammonia pressure decreased. The kinetics of decomposition of phosphine could be followed from a first order reaction at pressure  $10^{-4}$  to

<sup>15</sup> This calculation assumes that  $F'_a/F_n$  has the value unity, and that  $p = f(E_1, n) \frac{\alpha}{\beta}$  of equations (1) and (2) have the value unity. Often these quantities are less than unity,  $f(E_1, n)$  can however be greater than unity.

<sup>16</sup> Roberts work (*P.R.S.*, 1935, 152A, 445) suggests that after strong outgassing ( $> 2000^\circ \text{K.}$ ) and then exposure to residual gas from the walls of the apparatus, about 12 per cent. of the tungsten atoms only should remain denuded of oxygen under the conditions of our experiments. The remaining 88 per cent. very quickly takes up a stable atomic film of oxygen.

Worker.	Reaction.	Energy of Activation. (Cals.).	Temperature Measurement.

$5.0 \times 10^{-3}$  cms., to an intermediate order reaction from  $10^{-3}$  to  $5 \times 10^{-3}$  cms., and an approximate zero order reaction at pressures ca  $10^{-1}$  cms.

2. The rate determining step in both reaction involves a rearrangement of a hydrogen bond, since separations were observed in zero-point energy of 800 to 900 Cals. in the case of proto- and deutero-ammonia, and 550 Cals in the case of proto- and deutero-phosphine. The rate determining step in the phosphine decomposition is unimolecular.

3. Hydrogen and nitrogen have no influence upon the velocity of catalytic decomposition of ammonia. Oxygen-treated catalysts are temporarily poisoned but recover their activity at least in part as the reaction proceeds. The presence of a little gaseous oxygen alters the nature of the decomposition at  $1000^\circ$  K.

4. Energies of activation were measured by a compensating filament method which eliminates the effect of end losses. The energy of activation for the zero order ammonia decomposition was 42.4 K. Cals, and for the first order phosphine decomposition 25 K. Cals. The zero order phosphine decomposition gave an energy of activation of 32.2 K. Cals. Calculations were made of the absolute rates, which were respectively  $\frac{1}{1000}$  and  $\frac{1}{7000}$  for the ammonia and the phosphine decompositions, of the rate given by

$$- \frac{dn}{dt} = N_0 \cdot v_0 e^{-E/RT}.$$

It is a pleasure to thank Professor E. K. Rideal, F.R.S., for his interest and advice, and the 1851 Exhibition Commissioners for an Overseas Scholarship.

# A THERMODYNAMIC STUDY OF SYSTEMS OF THE TYPE $\text{PbCl}_2\text{--KCl--H}_2\text{O}$ AT $25^\circ\text{C}$ . PART V.

BY E. HUNTER AND A. J. ALLMAND.

*Received 8th November, 1935.*

In Parts I.<sup>1</sup> and II.<sup>2</sup> of this series, the results of measurements of E.M.F. at  $25^\circ\text{C}$ . on cells of the type

were described, the values of  $[\text{PbCl}_2]$  and of  $[\text{KCl}]$  being varied independently over the complete concentration range up to saturation. It was shown that, by suitable application of the Gibbs-Duhem equation<sup>3</sup>

$$N_1 d \ln a_1 + N_2 d \ln a_2 + N_3 d \ln a_3 = 0$$

to the experimental results, the values of  $a_2$  and of  $a_3$  could be calculated for all solutions in equilibrium with the three solid phases  $\text{PbCl}_2$ ;  $\text{PbCl}_2$ ,  $\text{KCl}$ ,  $1/3 \text{H}_2\text{O}$ ; and  $2\text{PbCl}_2$ ,  $\text{KCl}$ , utilising the  $a_1$  values given by the electrometric data, and taking the value of  $a_3$  for a saturated  $\text{KCl}$  solution (free from  $\text{PbCl}_2$ ) from the work of others. In a liquid phase containing  $\text{PbCl}_2$ ,  $a_2$  cannot be directly determined, but, on the other hand,  $a_3$  is given by the relative aqueous vapour pressure of the solution. Such measurements therefore not only can be used to check the values of  $a_2$  calculated for the saturated solutions mentioned above, but also, when applied, in conjunction with the known  $a_1$  values, to unsaturated solutions, or to solutions in equilibrium with solid  $\text{PbCl}_2$ , will permit of the calculation by the Gibbs-Duhem equation of the value of  $a_2$  in such solutions. The work described in this paper was undertaken with these two ends in view. The working out of the experimental technique took a considerable time, as did the measurements themselves. In addition, curious anomalies were encountered with solutions in the neighbourhood of  $0.8 \text{N}$ .  $\text{KCl}$ , the same region in which the E.M.F. and phase equilibrium data had also proved difficultly reproducible.<sup>4</sup> The upshot was that, except in this region, no results with unsaturated solutions were obtained.

## Apparatus.

We required a method capable of giving vapour pressures to an accuracy of  $0.1$  per cent., *i.e.* in our case, to about  $0.02$  mm. of mercury. Methods which could not be used in presence of a solid phase were inadmissible, and methods involving prolonged boiling of the solution to remove dissolved air were ruled out, in view of possible disturbance from hydrolysis of  $\text{PbCl}_2$ . Direct methods, depending on the lowering in height of a barometric column of mercury, were dismissed as not being capable of the

<sup>1</sup> *Trans. Faraday Soc.*, 1927, **23**, 470.

<sup>2</sup> *Ibid.*, 1933, **29**, 679.

<sup>3</sup>  $N_1, N_2, N_3$  and  $a_1, a_2, a_3$  refer to the molar numbers and activities of  $\text{PbCl}_2$ ,  $\text{KCl}$  and  $\text{H}_2\text{O}$  respectively, the  $a$  values all being taken as unity for the pure condensed phase.

<sup>4</sup> *Ref.* 2, p. 680.

requisite accuracy, apart from minor objections, and the differential pressure method perfected by Lovelace, Frazer and Sease<sup>3</sup> was clearly too laborious in view of the large number of data required. This limited us, at that time, to the use of a dynamic or streaming technique, and we finally settled on the recently devised method of Pearce and Snow,<sup>4</sup> which promised both the required accuracy and relatively easy and rapid manipulation.

In this method, a stream of electrolytic gas is passed at a constant rate of flow, controlled by an ammeter, through a series of saturators of special design, immersed in a thermostat and containing the solution under experiment. The aqueous vapour is caught in absorption tubes and weighed. From the number of mols. of electrolytic gas passed, exactly known by including a silver coulometer in the electrolysis circuit, the weight of water carried forward, and the barometric pressure, the vapour pressure of the solution is calculated by direct application of Dalton's Law. We employed essentially the apparatus as described by Pearce and Snow, introducing one or two modifications found by experience to give more certain and reproducible results. The **electrolysers**, six in number, were connected in series with an adjustable resistance, an ammeter and the 100-volt D.C. main. A coulometer could be included in the circuit as and when desired. Each consisted of a 3-litre wide-necked bottle, charged with 25 per cent. NaOH, and closed by a cork driven flush with the top level of the bottle, through which passed the gas outlet and two conical ebonite bushes which carried the electrodes. After filling and inserting the cork, the whole was sealed by a thick cap of paraffin wax. The electrodes were vertical concentric cylinders of nickel gauge, 4.5 inches high and 2.3 inches in diameter, their edges being rivetted by nickel wire into slots cut in  $\frac{1}{4}$ -inch nickel rods, which passed through the ebonite bushes mentioned above. A tubular glass separator prevented any possibility of chance contacts between the electrodes.

The **coulometer** consisted of a 150 c.c. platinum crucible, in which was suspended a pure silver rod anode, surrounded by a porous alundum cup. The composition and purity of solution, current density, etc., were in accordance with the usual standard specifications. The combined output of the electrolysers passed along a delivery tube, where its pressure was measured by a **water U-manometer**, through a **regulating tap**, to the barrel of which was sealed a long glass arm to ensure accurate setting, and to the **pre-saturator**. This was about 10 inches long, and of the pattern designed by Bichowsky and Storch<sup>5</sup> and used by Pearce and Snow. It was charged with water, and kept at a steady temperature between 25°-27° by electrical heating, the whole being lagged with asbestos wool. The gas current, supersaturated with aqueous vapour, then passed to a battery of eight further **saturators** of the same type as the pre-saturator, arranged in series in a thermostat at 25°. The first seven contained the solution under investigation and the last was empty. Slight condensation of water took place in the first saturator, equilibrium was finally adjusted in numbers 2-7, and the absence of any trace of liquid deposit in 8 at the end of a run was looked on as showing that no spray was being carried forward.

The gas finally emerged through a vertical tube from the end of the last saturator. This was electrically heated above water level to 40°-50° C. to prevent any possible loss of water by condensation, and terminated in a mercury-seal cup, to which the **absorber** was connected. This contained glass wool, cut into short lengths, and coated with  $P_2O_5$  by shaking the two materials together. The packing had the advantages of large absorbing surface, lightness and negligible resistance to flow. The original pattern of U-tube absorber used was modelled on that of Pearce and Snow. Occasional difficulty when filling, owing to  $P_2O_5$  getting between the sides of

<sup>3</sup> *J. Amer. Chem. Soc.*, 1916, **38**, 515.

<sup>4</sup> *J. Physic. Chem.*, 1927, **31**, 231.

<sup>5</sup> *J. Amer. Chem. Soc.*, 1913, **37**, 2696, Fig. 2.

the U and the tap barrels, led to its replacement by one closed by ground glass caps fitting *over* cones ground on the *outsides* of the limbs of the U. The apparatus train terminated in a **guard tube** containing  $\text{P}_2\text{O}_5$ .

The most important modification in the apparatus as compared with that of Pearce and Snow was the introduction of the regulating tap and manometer. With the electrolyzers connected directly on to the pre-saturator, it was found impossible to obtain a steady rate of flow of gas through the saturators, the gas tending to bubble out through the apertures on the lower side of the inclined tubes, instead of passing up inside the latter. By working with a steady pressure of about 20 cm. of water inside the electrolyzers, this trouble was completely avoided, and a smooth flow of the required rate obtained. The gas pressure in the saturators themselves was of course not affected by this procedure.

A few other points of practical interest may be briefly mentioned. (i) The actual rate of flow was limited by the capacity of the coulometer and by the necessity of avoiding any spray production. A current of 0.35–0.4 amp. was found suitable under our conditions. (ii) The optimum temperatures of the pre-saturator ( $25^\circ\text{--}27^\circ\text{C}$ .), and of the exit tube from the saturators ( $40^\circ\text{--}50^\circ\text{C}$ .) were worked out from experience. In the latter case, too high a temperature was found to lead to mercury being carried forward from the mercury seal into the absorber, whilst too low a temperature resulted in excessive condensation of moisture in the side arm of the latter. (iii) The packing of the absorber required care. If done too tightly, the increased resistance to gas flow caused a rise of pressure above atmospheric in the last saturator (the method of calculation assumes this to be one atmosphere) leading to low results. Any such effect was made evident by rises in pressure in the mercury seal and in the gas-generator manometer. It was only once experienced during the work. Towards the end of the experiments, a small manometer tube sealed into the cap on the filler of the last saturator, gave direct evidence that the pressure inside the latter was atmospheric. (iv) When filling the saturators with solution at  $35^\circ$  (see later), there was a tendency towards formation of a condensed film of moisture on their upper inside surfaces whilst cooling to  $25^\circ$ . Until this had been swept away by the stream of gas, the measured vapour pressures naturally tended to be high, subsequently falling to the correct value. In practice, the trouble was readily avoided by tilting the saturators to and fro after filling.

### Experimental Procedure.

The heating currents were switched on and the cleaned and dried saturators placed in the thermostat and connected up. Pure water was put in the pre-saturator. Some 600 c.c. of the solution under examination were prepared at  $60^\circ\text{--}70^\circ$  by the addition of the requisite amounts of KCl and  $\text{PbCl}_2$  (analytical reagents) to boiled out distilled water. When using solutions saturated with  $\text{PbCl}_2$  or one of the double salts, about 20 per cent. of  $\text{PbCl}_2$  over and above that required to form the actual saturated solution at  $25^\circ\text{C}$ . was used. After cooling to  $35^\circ$ , the solution was charged into saturators 1–7, the last being left empty. Residual solution was kept in a vessel in the thermostat, and subsequently analysed. The absorber was filled, air dried by passage over 1 m. of  $\text{CaCl}_2$ , followed by 1 m. of  $\text{P}_2\text{O}_5$ , drawn through it for thirty minutes,\* the absorber then cleaned by wiping and hung with a suitable counterpoise in the balance case. The platinum dish of the coulometer was cleaned, heated to  $150^\circ$ , and cooled in a dessicator. The electrolyzers were switched on, without the coulometer in circuit, and gas passed through the saturators overnight.

On the following day, absorber and platinum dish were weighed, the coulometer assembled, the absorber fitted with the guard tube and,

\* Preliminary experiments showed both that the air stream was sufficiently dried and that no  $\text{P}_2\text{O}_5$  was carried forward in this process.

simultaneously, the coulometer switched into the circuit and the absorber attached to the mercury seal of the outlet from the saturators. A run lasted five hours. Every hour the barometer was read to 0.1 mm., and its pressure corrected to 0° C. and 45° latitude. At the end of the run, absorber and coulometer were simultaneously removed. Dry air was sucked through the former for thirty to forty minutes, thus replacing the electrolytic gas, and carrying forward on to the  $P_2O_5$  any moisture condensed in the side-tube. Absorber and counterpoise were then wiped clean, hung in the balance case, and weighed an hour later and on the following day. The solution was siphoned off from the platinum dish, the deposit washed with distilled water subsequently siphoned off, the dish heated to 150°, cooled in a dessicator, and weighed an hour later and on the next day.

The vapour pressure of the solution  $p$  is given by the expression

$$p = P \times \frac{\text{mols. water vapour}}{\text{mols. water vapour plus mols. hydrogen and oxygen}}$$

where  $P$  is the corrected atmospheric pressure. Inserting the electrochemical equivalent of silver, this becomes

$$p = P \times \frac{w_{H_2O} \cdot 18.016}{\frac{w_{H_2O}}{18.016} + \frac{w_{Ag}}{23.973}}$$

where  $w_{H_2O}$  and  $w_{Ag}$  represent the increase in weight of absorber and coulometer dish respectively.

### Results.

Table I. contains the results of measurements with pure water, with saturated solutions of KCl free from  $PbCl_2$ ,

and with a few solutions unsaturated with respect to both components, the KCl concentration usually being in the neighbourhood of 0.791 *M*. (59 grams KCl/1000 grams  $H_2O$ ). The relative pressures in the last column, as in the next Table, are calculated on the basis of the figure for  $p_0$  of 23.78 mm. obtained in Expts. 1 and 2.

Table II. contains the results of measurements on solutions saturated with a solid phase containing  $PbCl_2$ .

### Discussion.

In Fig. 1 the results of Table II. are plotted in the form of relative pressures against KCl molality, whilst Fig. 2 contains the data<sup>a</sup> up to

<sup>a</sup> All molalities mentioned in the text refer to KCl.

FIG. 1.

1.1 *M.* plotted on a larger scale. The dotted curves are the relative vapour pressure curve for solutions of KCl free from  $\text{PbCl}_2$ , plotted from the concordant data of Lovelace, Frazer and Sease,<sup>10</sup> Pearce and Snow,<sup>6</sup> and Hepburn.<sup>11</sup> The chain curve represents, down as far as 0.791 *M.* (point B—invariant point with  $\text{PbCl}_2$  and  $2\text{PbCl}_2$ , KCl as solid phases), the relative vapour pressures of the saturated solutions actually dealt with in this paper, as calculated in Part II. We should expect our own points to fall on this curve, which is clearly not the case. The concentration range 0.678–0.791 *M.*, inside which were observed the abnormally high vapour pressures italicised in Table II., obviously requires separate discussion. Apart from these experiments, inspection of the Table shows that, out of eighteen solutions on which two or more measurements were made, in ten cases the figures differed by 0.02 mm. or less, this being the standard we originally aimed at; whilst in four instances (at 0.204, 1.088, 1.65 and 3.17 *M.*) the discrepancies exceeded 0.04 mm. In two of these cases, extra measurements indicated one of the two discordant values to be the more probable. On seven solutions, one measurement only was made. Examination of Fig. 1 suggests that, in two of these cases (2.74 and 4.40 *M.*) the observed values were too high by perhaps 0.10 and 0.06 mm. respectively, but that the other measurements were of a much higher degree of accuracy.

Omitting these two doubtful values from consideration, it appears that, starting with the most concentrated solution (in equilibrium with both KCl and  $\text{PbCl}_2$ , KCl  $1/3 \text{ H}_2\text{O}$ ) and passing towards more dilute solutions, there is very little difference between calculated and observed values up to near the invariant point C (solid phases  $\text{PbCl}_2$ , KCl,  $1/3 \text{ H}_2\text{O}$  and  $2\text{PbCl}_2$ , KCl). The concentration here is 3.096 *M.*, and the calculated value of  $a_2$  0.8995. Table II. shows this to be one of the values actually obtained at 3.17 *M.*; the difference between found and calculated values in this region would be about 0.04 mm., the former being the higher figure. From this point down to 1.812 *M.*, there are unfortunately no experimental points available for comparison, no weight being laid on the single determination at 2.74 *M.*, as has already been mentioned. The course of the experimental curve from this concentration onwards appears reasonably well defined; it would seem to run above the curve

FIG. 2.

<sup>10</sup> *J. Amer. Chem. Soc.*, 1921, 43, 102.

<sup>11</sup> *Trans. Chem. Soc.*, 1932, 553.

for pure KCl solutions at a distance corresponding to  $\Delta p$  circa 0.04 mm. until near 1.3  $M.$ , then to rise rapidly to a maximum value of  $\Delta p$  circa 0.15 mm., then to approach the KCl curve and to cut it at about 0.7  $M.$ , passing beneath it and away to a maximum distance corresponding to about 0.15 mm., and finally to approach it again, finishing below it at a value corresponding to the vapour pressure curve of a saturated aqueous solution of  $\text{PbCl}_2$ .

The calculated curve, on the other hand, runs below the curve for the pure KCl solution, its distance steadily increasing from about 2  $M.$  downwards, until, at about 1  $M.$ , it reaches a maximum value where  $\Delta p$  is 0.15 mm.; after which it rises more rapidly, finally shooting upwards, crossing the KCl curve at 0.81  $M.$  and ending at 0.791  $M.$  (point marked by triangle) with a value of  $a_3 = 0.9822$ . Until 0.8  $M.$ , where the experimental and calculated curves cross, the former is above the latter, and by distances corresponding to values of  $\Delta p$  which are throughout much greater than the experimental error—thus, by about 0.1 mm. at 1.8  $M.$  and perhaps by 0.25–0.3 mm. between 1 to 1.2  $M.$  KCl, a region which corresponds to a concentration range on the equilibrium diagram over which  $[\text{PbCl}_2]$  is changing very slowly with change of  $[\text{KCl}]$ .<sup>12</sup>

We do not think that the data recorded in this paper can be seriously questioned; the reason for the discrepancy must lie in the E.M.F. figures from which the calculated curve was obtained, or in the graphical integration by means of which these data were worked up, using the expression

$$\int d \log a_3 = \int \frac{2N_2 - N_1}{N_3} \cdot d \log a_1$$

If we consider this integration between the invariant point C and a concentration just over 0.8  $M.$ , the point at which the experimental and calculated curves cross, then experimental and calculated values of  $\Delta \log a_3$  become identical, *i.e.* the area obtained by plotting  $f(N)$  or  $(2N_2 - N_1)/N_3$  against  $\log a_1$  over this concentration range is numerically correct, and the discrepancies under discussion are to be ascribed to incorrect correlation between the  $f(N)$  and the  $\log a_1$  values when plotting these against one another. This, in its turn, may be due either to incorrect or to insufficient E.M.F. data, the latter because interpolation of experimental values is necessary when drawing the graph of  $\text{E.M.F.}/N_2$  before carrying out the graphical integration. Inspection of Table II., Part II., shows that only five experimental values of E.M.F. were available between point C and  $N_2 = 1$ , whilst, between this concentration and 0.8  $M.$ , the experimental data were so discordant that recourse had to be made to extrapolation devices when estimating the figures finally used (Table III., *loc. cit.* 2).

Assuming our experimental results to be represented by the full line in Figs. 1 and 2, we have accordingly applied to them the above equation in the form

$$\Delta \log a_3 = \left( \frac{2N_2 - N_1}{N_3} \right)_{\text{mean}} \Delta \log a_1$$

The experimental curve was divided into a number of sections, each with its definite terminal figures for  $a_3$ ,  $N_1$  and  $N_2$  ( $N_3$  is always 55.5). The terminal values of  $(2N_2 - N_1)/N_3$  were calculated from the known

<sup>12</sup> See reference 2, Fig. 1.

composition of the liquid phase, and the mean value taken. This was divided into  $\Delta \log a_3$  obtained from the experimental data, and  $\Delta \log a_1$ , i.e. the increment in  $\log a_1$  when passing from one end of the concentration section to the other, thus calculated. When  $f(N)$  was plotted against  $\log a_1$ , the result was a strip of area equal to  $\Delta \log a_3$ . Commencing at the invariant point C ( $N_2 = 3.096$ ;  $f(N) = 0.1142$ ), where  $\log a_1$  is  $\bar{1}.2796$ , this procedure was followed down to  $N_2 = 0.9$ , the concentration range being divided into seventeen sections, a method which reduced to a minimum any inaccuracy involved in assuming  $f(N)$  to be a linear function of  $\log a_1$  inside any particular section.

The plane figure obtained was practically identical down to  $2.25 M.$  with that constructed when working up the E.M.F. data in Part II., in accordance with the fact that, over this concentration range, the experimental and calculated curves for  $a_3$  run close to and parallel to one another (Fig. 1). Below this point, the area of the new figure became progressively greater than that of the former one, corresponding to the increasing divergence between the experimental and calculated curves for  $a_3$ . At  $N_2 = 0.9$  ( $f(N) = 0.0326$ ),  $\log a_1$  was  $\bar{1}.8043$ , whereas the electrometric data, on which the former graphical integration was based, had given  $\bar{1}.762$ . When, using the expression

$$\log a_1 = (0.4837 - E)/0.02957,$$

the values of  $E$  were calculated systematically over the whole concentration range from the new diagram, it became plain that insufficiency of E.M.F. data was not responsible for the divergence between the experimental and calculated values of  $a_3$ . Down to  $2 M.$ , the calculated values of  $E$  fell on the old experimental  $E/N_2$  curve. But at lower concentrations they were below those actually determined, the discrepancy being about  $0.0005$  volt at  $1.5 M.$ , rapidly increasing below  $1.3 M.$ , reaching a maximum of  $> 0.002$  volt at  $1.05 - 1.1 M.$  (concentration of maximum difference between experimental and calculated  $a_3$  values), and then diminishing. The values of  $a_1$  electrometrically determined, as in the case just quoted, are lower than those calculated from vapour pressure measurements. Attention has already been drawn to the discussion in Part II of the discordant results obtained when experimenting in this concentration region, both when attempting to determine the exact shape of the equilibrium diagram and in the measurement of E.M.F. In the latter case, solutions presumed to be of the same composition made up at different times gave E.M.F.s differing by amounts up to  $0.0003$  volt. Returning to the  $f(N)/\log a_1$  diagram under discussion, a further point of considerable interest arises. In order to complete it, it must be carried to the non-variant point B, where  $\text{PbCl}_2$  is one of the solid phases and  $\log a_1$  consequently  $0.0$ . This non-variant point has been approximately (see Part II.) fixed at concentrations of KCl and  $\text{PbCl}_2$  which give a value of  $f(N) = 0.0283$ , a figure which will not be seriously affected by the uncertainty regarding the exact position of B. Taking these facts into account, the increment in  $\log a_3$  when passing from  $N_2 = 0.9$ , where  $\log a_1$  is  $\bar{1}.8043$ , to B *cannot be less than*  $0.0283$  ( $0.0 - \bar{1}.8043$ ), i.e.  $0.00554$  and will probably be greater. At  $N_2 = 0.9$ ,  $a_3$  (experimental) is  $0.975$  and  $\log a_3$   $0.9890$ . It follows that, at B,  $\log a_3$  will be *at least*  $0.9945$  and  $a_3$  *at least*  $0.9874$ . The  $f(N)/\log a_1$  diagram when completed graphically gives  $0.0400$  as the most probable value for  $\Delta \log a_3$  when passing from C to B. At C,  $\log a_3$  is  $\bar{1}.9549$ ; hence it is  $\bar{1}.9949$  at B and

$a_3$  is 0.9883. The experimental curve for  $a_3$  in Figs. 1 and 2 has been extrapolated in this way to point B (denoted by square on diagrams). Like the curve calculated from the E.M.F. data, it bends up very sharply at the end; but it must be realised that its construction in the present case does not involve any E.M.F. data other than the figures corresponding to the two non-variant points bounding the solubility curve of  $2\text{PbCl}_2$ , KCl. About the essential correctness of these, there can be no reasonable doubt.

The value of 0.9883 for  $a_3$  at B, obtained from these two E.M.F. measurements and our own vapour pressure data, lies then far above the two direct determinations (0.9767 and 0.9756—see Expts. 53 and 54, Table II.), which it would be natural to regard as normal, whilst falling below the third, abnormal value (0.9954—Expt. 52). It furnishes an independent reason for considering that the abnormal figures in general (italicised in Table II.) found between this value of  $N_2$  and 0.678 are not merely due to some unusual experimental error. Similar high vapour pressures recorded for unsaturated solutions in the same KCl concentration region are italicised in Table I. We ourselves, whilst being unable to explain their spasmodic appearance, do not doubt that they represent the actual vapour pressures exerted by the systems in question under the experimental conditions. They were never observed except with solutions of  $N_2$  values between 0.678–0.804 (50–60 grams/litre KCl). Four out of seven experiments with unsaturated solutions in this concentration range gave abnormally high vapour pressure values, and ten out of sixteen experiments with saturated solutions. The results of the sequence of Expts. 55–74 is of interest. Expts. 55–65 were on solutions between 1.65 *M*. and saturation and gave normal results; in Expt. 66,  $N_2$  was 0.782 and the vapour pressure exceptionally high; Expts. 67–70 (KCl 1.032 *M*. and saturated) gave normal results, whilst in 71–72,  $N_2$  lay in the critical range and the results were high; in Expt. 73,  $N_2$  was 0.536 and the vapour pressure normal, whilst Expt. 74 ( $N_2 = 0.804$ ) gave a very high figure.

One of the abnormal values (Expt. 78, Table I.) was given by a solution containing KCl only, its vapour pressure being almost 1 per cent. above the generally recognised figure. Unpublished measurements of Dr. L. Nickels have shown that the minimum of the viscosity-molality curve for KCl solutions at  $25^\circ\text{C}$ . lies at about 0.75 *M*., and the view that a "negative" viscosity is due to the depolymerising effects of the solute on the molecules of the solvent is well known. Monohydrate would, of course, have a very high vapour pressure at  $25^\circ$ , and it would only need a slight displacement of the normal equilibrium between it and its polymers to cause a considerable rise in the vapour pressure of water. These facts suggested that an intensive investigation of the vapour pressures of pure KCl solutions in this concentration region might give results of interest. Such work has been done, using a variety of experimental methods. Some very curious and some quite normal results have been obtained, and it is hoped shortly to publish them.

Omitting consideration of the abnormal region, the general course of our experimental curve furnishes evidence of the presence of complexes in solution, in agreement with their isolation in the solid state. At low KCl concentrations, the effects of the dissolved KCl and  $\text{PbCl}_2$  on the vapour pressure of the solvent tend to be additive. As [KCl] increases, complex formation becomes so important that the vapour pressures of the solutions actually exceed those of solutions of pure KCl of the same

KCl molality. Further increase in  $[KCl]$  causes this effect to become relatively less important, and the curves approach one another again. The observations made in the region of the abnormal vapour pressures, as also the sudden changes in slope of the experimental curve between 1 and 1.3  $M$ . show, however, that this simple conception is insufficient to explain completely the nature of the system.

Thermodynamic treatment of the experimental curve at KCl concentrations below B is impossible owing to the ill-defined values of  $a_3$  in the critical concentration range.

### Summary.

(1) The measurement at 25° C. of the aqueous vapour pressures of solutions containing KCl and  $PbCl_2$  in equilibrium with various solid phases, as also of certain unsaturated solutions is described.

(2) The results are not in agreement with previous calculations made from electrometric work carried out on the same system. An examination of the discrepancies leads to the conclusion that the electrometric data are of insufficient accuracy.

(3) Over a narrow concentration region, abnormally high aqueous vapour pressures, approaching that of pure water, were frequently observed. This region is the same one in which discordant analytical and E.M.F. data had previously been obtained.

These experiments were carried out during the sessions 1927-29. One of us (E. H.) wishes to acknowledge his indebtedness to the Department of Scientific and Industrial Research for a maintenance grant received by him over this period.

## THE ABSORPTION SPECTRUM OF SULPHUR TRIOXIDE.

BY E. FAJANS AND C. F. GOODEVE.

*Received 17th December, 1935.*

No measurements of the absorption spectrum of pure  $SO_3$  have been recorded. Dutt<sup>1</sup> studied the absorption of  $SO_2$ - $SO_3$  mixtures and claimed to be able to eliminate the effect of the former. "Continuous absorption" from 3300 to 2600 Å and from 2300 Å downwards was found and attributed to  $SO_3$ . The present investigation in which the  $SO_2$  content is reduced to a very low value, has not confirmed these conclusions.

### Experimental.

The absorption spectrum of  $SO_3$  was examined by means of a small Hilger quartz spectrograph, E. 370, and later by a medium Hilger quartz, E. 3. Wave-lengths were determined by comparison with a copper arc. A hydrogen discharge tube was used as a source of continuous ultra-violet

<sup>1</sup> A. K. Dutt, *Proc. Roy. Soc.*, 1932, **137A**, 366.

light. Absorption tubes of 54 cm. and 346 cm. lengths were used. Joints between quartz and glass were sealed with sodium silicate and aged by leaving in contact with gaseous  $\text{SO}_3$  for some days. As  $\text{SO}_3$  attacks mercury even when dry, pressures were measured by means of a calibrated quartz Bodenstein gauge.<sup>1</sup>

The  $\text{SO}_3$  was prepared by distilling *in vacuo* pure fuming sulphuric acid and fractionating between traps cooled in liquid air. The first and last fractions were rejected by sealing off the requisite traps. Removal

FIG. 1.—The absorption curve of sulphur trioxide (full line) and of sulphur dioxide (dotted line—approximate curve).

of the dioxide by fractionation is insufficient as it is reproduced rapidly during a measurement by photodecomposition of the  $\text{SO}_3$ . Complete elimination of the absorption bands of  $\text{SO}_3$  down to 2200 Å. was obtained by streaming the purified gas rapidly through the absorption tubes between traps at the ends.

The first photographic exposure was taken with liquid air on the traps and the intensity of the light reduced a definite amount by means of a rotating sector. The liquid air was then removed and the desired pressure

<sup>1</sup> J. W. Goodeve, *Trans. Faraday Soc.*, 1934, 30, 501.

and velocity of flow of  $\text{SO}_2$  obtained by careful regulation of the temperatures of the end traps. With the sector open a second exposure through the gas was taken in an adjacent position on the photographic plate. A third adjacent spectrum was taken identical to the first, to test the constancy of the light source. The extinction coefficient  $\alpha$  was obtained for the wave-length of the "match point," by the equation

$$\alpha = \frac{1}{p \cdot l} \cdot \log_{10} \frac{I_0}{I_r} = \frac{1}{p \cdot l} \cdot \log S,$$

where  $p$  is the pressure in mm. of Hg,  $l$  the length of the tube in cm., and  $S$  the sector angle. The molecular extinction  $\epsilon$  was calculated by the equation,

$$\epsilon = \frac{1}{cl} \cdot \log_{10} S,$$

where  $c$  is the concentration in gram molecules per litre, calculated assuming the temperature to be  $18^\circ \text{C}$ . Pressures in the range of 1 to 160 mm. were obtained and could be kept constant to within 5 per cent., except below 10 mm.

### Results.

The absorption spectrum of sulphur trioxide was observed between 3000 and 2200 Å and found to consist of weak diffuse bands superimposed on a continuous background. The logarithms of the extinction coefficients

FIG. 2.-The absorption in the region of the diffuse bands.

obtained as described above are shown in Fig. 1, plotted against frequency. It was found impossible to obtain reliable measurements below 2200 Å. owing to the very strong  $\text{SO}_2$  absorption in this region.

The observed diffuse bands were of an unusual type. The maxima of absorption were flat and the minima sharp as indicated diagrammatically in Fig. 2. The distance between the minima was found to be approximately constant and equal to 430 W.N. It may be possible at some time to correlate this with a fundamental frequency of the molecule. The diffuse bands appear to extend to about 2700 Å., but above 2500 Å. they could not be measured with certainty. These bands cannot be attributed to  $\text{SO}_2$ , as they occur at the position of minimum absorption of the latter. It is unlikely that they are due to other impurities as they always appeared with the same intensity under the same conditions. They are probably predissociation bands.

### Discussion.

The observations recorded here indicate that the absorption of  $\text{SO}_2$  is of a different character and in a different position from that found

by Dutt. He claims that "it is possible to eliminate the  $\text{SO}_2$  bands from the plate by putting an excess of oxygen in the absorption chamber and then filling it up with  $\text{SO}_2$  vapour. According to the law of mass action the partial pressure of  $\text{SO}_2$  is very considerably reduced by the addition of  $\text{O}_2$ ." It is well known that even in the presence of a catalyst  $\text{SO}_2$  does not react with oxygen at room temperature.

Approximate values of the extinction coefficients of  $\text{SO}_2$  have been calculated from the results of Garret<sup>3</sup> and from a photometric curve of Kornfeld and Weegmann.<sup>4</sup> These are indicated by the broken line in Fig. 1. It is seen that at some wave-lengths one part in one thousand of  $\text{SO}_2$  is sufficient completely to mask the absorption of  $\text{SO}_2$ . The coincidence between the limits of absorption found by Dutt and those for  $\text{SO}_2$ , coupled with the above argument, leads to the conclusion that his observations were due to the presence of the dioxide.

The decomposition of  $\text{SO}_2$  into  $\text{SO}$  and normal O atoms requires 81.3 K cal. (Landolt-Börnstein). This corresponds to a wave-length of 3500 Å. It is probable that this is the primary photochemical process in most of the ultra-violet range. Coehn and Becker<sup>5</sup> found that  $\text{SO}_2$  decomposes photochemically by light transmitted through "Uviol-glass" (transparent to about 2500 Å). At wave-lengths below 2500 Å. it is possible for excited D oxygen atoms to be produced.

Our thanks are due to Professor Donnan for his interest and encouragement in this work.

## THE PHOTOCHEMICAL FORMATION OF ORGANIC DIRADICALS. PART III.\* INVESTIGATIONS ON ANTHRACENE, THE FULGIDES, THIO-PHOSGENE AND THEIR DERIVATIVES.

BY ALEXANDER SCHÖNBERG.

*Received 29th November, 1935.*

1. In a previous communication,<sup>1</sup> I showed that the remarkable behaviour of rubrene towards oxygen in light is accounted for in the following way. Rubrene in the dark has the formula I, in agreement with the fact that either in solution or in the solid state, it is stable to air provided it is kept in the dark. If the solution, however, is irradiated a photoequilibrium occurs between the normal form and the diradical

\* *Annalen*, 1935, **518**, 299; *Ber.*, 1934, **67**, 633.

<sup>1</sup> *Ibid.*, 1934, **67**, 633.

form (II). The latter, containing as it does two trivalent carbon atoms, can form a peroxide (III), by the addition of oxygen.

Recently I pointed out further <sup>2</sup> that chromanorufen (IV) and tetraphenyl-*p*-quinodimethane (VI) are to be regarded as the analogues of rubrene. Their solutions in the absence of light are extremely stable to oxygen, but in light they quickly lose their colour, as in irradiated solutions a photoequilibrium is set up between the normal and diradical forms (V and VII). The latter, on account of their trivalent carbon atoms, can react with oxygen.

2. It will now be shown that similar considerations can be applied to anthracene and its derivatives. The assumption that anthracene and its derivatives can exist as diradicals has been made repeatedly. For example, Ingold and Marshall <sup>3</sup> showed that a solution of 9-10-diphenylanthracene (VIII) changes its colour on warming and explained this fact by assuming that heating shifts the equilibrium between the normal form (VIII) and the diradical form (IX) in favour of the latter.

<sup>2</sup> *Annalen*, 1935, 518, 300.

<sup>3</sup> *J. Chem. Soc.*, 1926, 3080.

Dufraisse and Étienne<sup>4</sup> also recognised that 9-10-diphenylanthracene is capable of forming an equilibrium mixture  $\text{VIII} \rightleftharpoons \text{IX}$ . Clar<sup>5</sup> states that the characteristic properties of anthracene derivatives can best be accounted for by equilibrium formulæ of the type represented by  $\text{X} \rightleftharpoons \text{XI}$ . In the case of one derivative, 2-3-6-7-dibenzanthracene, a deep coloured compound, he assumes that it exists *only*<sup>6</sup> in the diyl-form XII.

All such considerations deal with the occurrence of diradicals in *thermo*-equilibrium with the normal molecules. This assumption, however, is not in accordance with the following facts. No peroxide formation in the dark has been observed in the case of anthracene, 9-10-diphenylanthracene, and 2-3-6-7-dibenzanthracene. Further, magnetic measurements on 2-3-6-7-dibenzanthracene, contrary to Clar's assumption, have shown that this compound does not exist entirely in the diradical form. If in thermoequilibrium its molecules exist in the diradical form, their concentration is so small that they cannot be detected by magnetic measurements.<sup>7</sup> Summarising, it can be said that on the whole there is little experimental evidence for the existence of a *thermo*equilibrium of diradicals in the field of anthracene, though the work of Ingold<sup>8</sup> shows that in certain cases such equilibria probably occur.

I believe, however, that in irradiated solutions of the above compounds a *photo*equilibrium exists between the normal and the diradical forms. On this assumption it is easy to explain why *irradiated* solutions of anthracene, 9-10-diphenylanthracene, and 2-3-6-7-dibenzanthracene react with oxygen. It is simply a question of the action of oxygen on the trivalent carbon atoms of the *photodiradicals* IX, XI, and XII. The formation and structure of the oxidation products of anthracene and 9-10-diphenylanthracene have been definitely established by the investigations of Dufraisse and Gérard,<sup>8</sup> and Dufraisse and Étienne.<sup>9</sup> They possess the formulæ XIV and XV respectively. The structure of the compound formed by the action of oxygen on 2-3-6-7-dibenzanthracene is unknown.

<sup>4</sup> *Comptes rendus*, 1935, **201**, 280.

<sup>5</sup> *Ibid.*, 1930, **63**, 2967.

<sup>8</sup> *Comptes rendus*, 1935, **201**, 428.

<sup>6</sup> *Ber.*, 1932, **65**, 503.

<sup>9</sup> *Ibid.*, 280.

The photopolymerisation of anthracene to dianthracene (XIII) is also most readily explained by the assumption that the diradical XI is an intermediate. It is not proposed to discuss in this paper whether XIII is formed by the direct combination of two diradicals or by means of a more complicated process.<sup>10, 10a</sup>

The objection might be raised that a photodimerisation of 9-10-diphenylanthracene has not yet been observed, and this used as an argument against the theory of biradical formation in irradiated solutions of 9-10-diphenylanthracene (IX). The non-occurrence of the dimeric 9-10-diphenylanthracene XVI, however, is probably due to its thermolability and, in my opinion, does not contradict the theory outlined above. From our knowledge of the relationship between constitution and stability to heat, the compound XVI must be thermolabile, and, indeed, considerably more labile than the rather thermolabile dianthracene which decomposes above 150° into two anthracene molecules.<sup>11</sup>

It may be for this reason that the presence of XVI could not be detected, possibly the compound at room temperature being incapable of existence or of existing for only a limited time. To avoid a lengthy discussion, I will content myself by pointing out the following analogies: Dianthracene (XIII) is related to the compound XVI as 1-1-2-2-tetraphenylethane (relatively thermo-stable) to hexaphenylethane (thermolabile); as 1-2-diphenylhydrazine (relatively thermo-stable) to tetraphenylhydrazine (thermolabile); or as trithiobenzaldehyde (XVII) (thermo-stable) to trithiobenzophenone (XVIII). This last compound is so thermolabile that no method for synthesising it has yet been found.

<sup>10</sup> Cf. Weigert and Jackh, *Naturwissenschaften*, 1927, 15, 124. The above ideas of the photochemical transformation of a system of conjugated double bonds to a biradical system

have nothing in common with the considerations of other authors who assume that in irradiated solutions of anthracene the following process takes place, involving the rupture of an ethane linkage. (Cf. Weigert, *Naturwiss.*, 15, 124; Weigert and Pruckner, *Z. physik. Chemie, Bodenstein Festband*, 1931, 775).

<sup>10a</sup> Formula XI. contains trivalent carbon atoms, one of the valences of each of these atoms being saturated with hydrogen. Such an assumption finds support in the existence of a similarly built monoradical formed by a reaction in the dark. (Cf. Wittig and B. Obermann, *Ber.*, 1935, 68, 2214) (added in proof).

<sup>11</sup> W. Jackh, *Dissertation, Leipzig*, 1927, p. 21.

Reactions which might be expected to form it, yield instead its dissociation product thiobenzophenone.<sup>12</sup>

3. The fulgides possess certain properties which have been difficult to understand, but which can be readily explained by the diradical theory as the following example shows. Tetraphenyl-fulgide (XIX) is changed by *light* into the two isomers XXI and XXII.<sup>13</sup>

This reaction is difficult to understand if one starts from formula XIX for tetraphenylfulgide. Assuming, however, that it is a question of a reaction of the diradical XX, then the reaction can be simply explained. There are many analogies to this mechanism in the field of free radicals. For example,<sup>14</sup> the formation of XXIV from XXIII in the course of a dark reaction.

W. Schlenk and E. Bergmann<sup>15</sup> have assumed that the molecules of certain fulgides are in *thermo*equilibrium with diradicals and that the concentration of the latter increases with rise in temperature. In this way they have tried to explain the reversible alterations in colour which certain fulgides undergo on warming.

<sup>12</sup> Cf. Schönberg, *Ber.*, 1929, **62**, 195.

<sup>15</sup> *Ausführliches Lehrbuch der organischen Chemie*, Vol. I., p. 520.

4. The photochemical change of maleic and fumaric acids into one another has been explained by the assumption that both acids possess the same excited electron state (*Elektronenzustand*) with a single carbon to carbon linkage brought about by absorption by molecules of either acid. Olsen<sup>16</sup> formulates the process as follows:

There exists, from the standpoint of the biradical theory, great similarity between maleic and fumaric acids on the one hand and the compounds I, IV, VI, and VIII on the other, since the last four compounds can also be converted by light into diradicals. Whether or not this similarity is quantitative will not be fully discussed here. If the analogy holds quantitatively, then for example in the case of diphenylanthracene the equation  $\text{VIII} + h\nu = \text{IX}$  must hold, but the formation of the diradical IX may be more complicated, e.g.

$\text{VIII} + h\nu = \text{diphenylanthracene}^*$ . Diphenylanthracene\* means that the molecule is in an excited condition which differs from IX, and that IX results from diphenylanthracene\* by secondary reactions in the dark, possibly through collision with one or more molecules of VIII or of the solvent. Similar modes of formation of the other diradicals which have been discussed in this paper can be postulated.

5. The capacity of diradicals to exist in equilibrium in the dark has long been known.<sup>17</sup> In the case A, the accepted view has recently been

confirmed by magneto-chemical measurements.<sup>18</sup> It will be very difficult to prove the existence of diradicals in irradiated solutions of I, IV, VI, VIII, X, and XIX by magnetic measurements. The equilibrium point between the normal and the corresponding diradical depends among other things on the intensity of the effective frequency of the light used. Where the life-period of the photo-diradical is short, it will be difficult to obtain photo-systems in which the concentration of the diradical form is reasonably great in comparison with the concentration of the normal form. Such conditions, however, are necessary for the detection of diradicals by magnetic measurements (*cf.* the lack of sensitivity of the known experimental methods).

Eugen Müller<sup>19</sup> states that radiated solutions of rubrene cannot be

<sup>16</sup> *Trans. Faraday Soc.*, 1931, **27**, 69. Compare also K. F. Bonhoeffer and P. Hartack, *Grundlagen der Photochemie*, Dresden and Leipzig, 1933, p. 269.

<sup>17</sup> *Cf. Schlenk and Brauns, Ber.*, 1915, **48**, 716.

<sup>18</sup> Müller and Müller-Rodloff, *Annalen*, 1935, **517**, 144.

<sup>19</sup> *Z. Elektrochem.*, 1934, **40**, 542.

distinguished from non-irradiated solutions by magnetic measurements. His results have been used as an argument against the diradical theory.<sup>20</sup> This, however, is not applicable for the reasons given above. In addition in Müller's paper no details whatever are given about the optical conditions used. (Intensity of the radiation frequency, conditions of absorption.) Müller himself seems to hold that his experimental results do not contradict the diradical theory.<sup>21</sup>

It might be asked why, in irradiated solutions of rubrene, there is considerable chemical reactivity of the diradicals although their concentration in photo-chemical equilibrium is very small. It should be pointed out that for the *chemical* properties of the photo system  $I \rightleftharpoons II$  the decisive factor is not the relative concentration of II but the quickness with which II is regenerated when the photo-equilibrium  $I \rightleftharpoons II$  is disturbed by chemical reactions. This is the reason why irradiated solutions of rubrene react quickly with oxygen even when the relative concentration of the biradical form is very small. All that has been stated above about rubrene solutions can be applied to other photosystems.

6. It must on no account be assumed that the photo-chemical formation of diradicals is limited to the formation of two trivalent carbon atoms within one molecule. A case in point is that of thiophosgene (XXVII). Recently, with Stephenson,<sup>22</sup> I showed that the photodimerisation of thiophosgene does not yield the compound XXX as had previously been assumed, but that the photodimer had the structure XXIX.<sup>22a</sup> The process is analogous to that of the dimerisation of anthracene, and it can be assumed in this case also that in the irradiated solutions of thiophosgene a *photo-chemical* equilibrium exists ( $XXVII \rightleftharpoons XXVIII$ ). Evidence for the analogy is further found in the properties of the dimers XIII and XXIX which depolymerise on heating.

The quantum sensitivity of the photo-chemical polymerisation of anthracene has been frequently investigated.<sup>23</sup> It might perhaps be desirable to test the above views and hypotheses of the polymerisation of anthracene in the system  $XXVII \rightarrow XXIX$ , but circumstances do not permit me to do so. Since thiophosgene is red and the photodimer XXIX colourless, it would be easy to estimate colorimetrically the concentration of thiophosgene in any given system. Consequently, the quantum yield should be easily determined.

Unfortunately, the number of organic photo-chemical reactions which have been investigated with regard to their quantum sensitivity is small, since only a few reactions are suitable for such investigations. I might mention in this connection the photodecomposition of the colourless ion

<sup>20</sup> Cf. Richter-Anschütz, *Chemie der Kohlenstoff Verbindungen*, 12th edition, Vol. II., part 2, p. 651, 1935.

<sup>21</sup> *Annalen*, 1935, 517, 146.

<sup>22</sup> *Ber.*, 1933, 66, 567.

<sup>22a</sup> This formula has just been confirmed by Delépine and co-workers, *Bull. Soc. Chim.*, 1938, 1969 (added in proof).

<sup>23</sup> Luther and Weigert, *Z. physik. Chemie*, 1905, 51, 297; 1905, 53, 385; Weigert, *Ber.*, 1909, 42, 850; Weigert and Jackh, *Naturwissenschaften*, 1927, 15, 124; Byk, *Z. physik. Chemie*, 1908, 62, 454.

$\alpha\beta$ -diphenylthiol - $\alpha\beta$ -di (diphenylene-ethane) XXXI.<sup>24</sup> The decomposition product XXXIa is red, so that it is easy in this case also to estimate the quantity of decomposition product colorimetrically and from this the quantum sensitivity.

The author thanks Dr. Neil Campbell for his assistance in the translation of the manuscript, and acknowledges his profound gratitude to Professor G. Barger for his hospitality.

### Summary.

1. The author shows that from his earlier work on irradiated solutions of rubrene a photoequilibrium ( $I \rightleftharpoons II$ ) between the normal and diradical form is set up. In order to explain the different chemical properties of irradiated solution of certain anthracenes, fulgides, and thiophosgene in comparison with those of non-irradiated solutions, he assumes that an analogous photoequilibrium occurs. The phenomena of photo-oxidation, photoisomerisation, and photopolymerisation in such solutions are thus explained.

2. The difficulty or impossibility of establishing the presence of diradicals in these photoequilibria by magneto-chemical measurements is discussed.

3. It is shown, from the structure of the photodimer of thiophosgene previously advanced by the author, that the photopolymerisation of thiophosgene is an analogous process to that of the photopolymerisation of anthracene. The consequences arising from this are discussed.

4. By considering the relationship between constitution and stability to heat of organic compounds, it is explained why the dimers of certain photodiradicals are incapable of existence.

### REVIEWS OF BOOKS.

**The Teaching of Chemistry in the Universities of Aberdeen** (Aberdeen University Studies No. 112). By ALEXANDER FINDLAY (Aberdeen: The University Press, 1935. Pp. viii + 92).

Professor Findlay has traced the history of the teaching of Chemistry in Aberdeen from the earliest period until 1914. A Chair of Chemistry was founded in 1793, although private lectures on the subject had been given in 1783. One of the professors was Thomas Clark (1833-1860), who discovered metaphosphoric acid and invented the water-softening process. Other well-known names are Carnelley and Japp: the account closes with

the retirement of the latter. Professor Findlay has dealt with his materia in a very skilful way, and the result is a work of scholarship which is at the same time full of interest on the personal side.

J. R. P.

**Principles and Applications of Electrochemistry. Vol. I. Principles.**

By H. JERMAIN CREIGHTON. John Wiley & Sons., Inc., New York ; Chapman & Hall, Ltd., London. Third edition, 1935. Pp. 502. Price 20s.

The continued demand for Professor Creighton's well-known book has necessitated the publication of a third edition, and the author has taken the opportunity to re-write certain portions and to add some new matter. In addition to the topics generally included in the subject of electrochemistry the book contains short chapters on electrokinetic phenomena and on the electrochemistry of gases ; fused electrolytes are also mentioned from time to time. The material added in the present edition deals chiefly with the measurement of conductivity and application of the results for the purpose of testing the Onsager equation, with the determination of transport numbers by the moving-boundary method, with potentiometric titration, and with the glass electrode. A number of new references are also to be found in other sections of the book. It is perhaps surprising that the chapter on the relationship between chemical structure and the dissociation constants of acids and bases is unaltered from the first edition : as this subject has moved so definitely into the province of organic chemistry in recent years the author might find it advisable in a later edition to leave this short portion out of the book entirely. The highly speculative, if picturesque, method for the calculation of ionic hydration proposed by Remy could also be omitted without serious loss. The section on the activity of strong electrolytes is short but quite adequate for the purpose of the book ; in it the author says "the concept of activity has been used very extensively in the recent study of strong electrolytes, and its utility has been fully justified." Nevertheless it is a matter for regret that apart from the chapter mentioned and the following one on theories of strong electrolytes, the activity idea is not used, not even in the discussion of E.M.F. Apart from this omission, which may have been made intentionally to simplify the treatment, the book forms a useful introduction to many aspects of electrochemistry, and its excellent production and clear printing should make an appeal to students of the subject.

S. G.

**The Chemistry of Rubber.** By H. FREUNDLICH. London : Methuen, 1935. Pp. xi + 72. Price, 2s. 6d. net.

This short essay deals with the colloid chemistry of latex and raw rubber, together with a few remarks on vulcanisation and plantation history, so that the title is somewhat misleading. The treatment is too compressed to make any part of the book adequate, but it serves as an interesting summary of the outstanding colloid problems of the industry. A stimulating feature is the number of difficult questions stated and left as unanswerable in the present state of knowledge.

T. R. D. and B. D. P.

**Étude Thermodynamique de la Tension Superficielle.** By RAYMOND DEFAY. Paris: Gauthier-Villars & Cie, 1934. 372 pp.

Although the two monographs forming this book deal with related subjects, either can be read independently of the other. They will be reviewed separately.

Part I. Formules générales. Affinité et vitesse d'adsorption. Catalyse. Équilibre. Influence de la courbure.

Gibbs' classical work on "The equilibrium of chemical substances" deals almost entirely with the thermodynamic conditions governing systems in complete equilibrium, but Gibbs' methods are easily extended to deal with systems only in partial equilibrium. In Defay's first monograph he applies these methods to chemical systems in which there is thermal and mechanical equilibrium throughout the system and chemical equilibrium in each phase, but not necessarily equilibrium between the surfaces and the bulk phases. Defay derives over 500 equations for these systems. They appear to be correct without exception, but the majority of them are neither very interesting nor very useful. Most of them answer questions of the type "how does the surface tension depend on the temperature (or on the pressure) when the compositions of all bulk phases and all surfaces are kept unchanged, a condition practically impossible to fulfil?" Yet the most obviously useful questions are ignored, such as: how does the surface tension depend on the temperature (or on the pressure) when equilibrium is maintained throughout the system? Many of the formulæ are effectively mere repetitions of others depending, for instance, on a change from mole fractions to mole ratios.

Defay follows De Donder in replacing Gibbs' conception of the "number of independent components" by the total number of chemical species diminished by the number of distinct chemical reactions between them. This seems to complicate the formulæ without any compensating advantage. It is admittedly difficult to define clearly and simply the number of "independent components," but no more so than the number of "distinct" chemical reactions. The author conscientiously gives a mathematical definition of this number, which is far from simple, but it is placed anomalously in the second monograph.

The author goes to much pains to show that the position of the geometrical dividing surface is not arbitrary. He appears to have overlooked Gibbs' clear pronouncement on this point. "The value of  $\sigma$  is therefore independent of the position of the dividing surface when this surface is plane. But when we call this quantity the superficial tension, we must remember that it will not have its characteristic properties as a tension with reference to any surface. Considered as a tension its position is in the surface which we have called the surface of tension and nowhere else." (*Collected Works*, p. 234.)

This work, in common with other work by De Donder and his school, is, in the reviewer's opinion, marred by the attempt to apply thermodynamics to chemical kinetics. All progress in this field has come from considerations of molecular mechanism, and the idea that a reaction rate is determined by the affinity of the reaction and a chemical "viscosity" is probably admitted to be abortive by all chemists except the De Donder school.

The notation used is consistent, but unattractive. For instance the

symbol  $\mu$  is used to denote the chemical potential per mole and  $B$  is used for the chemical potential per unit mass, for which Gibbs used  $\mu$ . If a separate symbol were necessary, which is questionable, surely something more appropriate than  $B$  might have been used. If this were an isolated instance it would not be worth mentioning, but it is only one of many. When twenty or thirty symbols have to be memorised it is important that they be chosen in such a manner as not to make the memorisation unnecessarily difficult.

Part 2. Les extremes de tension superficielle et l'indifférence des systèmes capillaires.

This monograph contains an exhaustive discussion of the number of degrees of freedom of systems in equilibrium containing curved surfaces. In the special case that all the surfaces are plane this number is given by the familiar "phase rule." The conditions for the surface tension to have a stationary value for constant temperature or for constant pressure or for both constant are derived in detail. It is emphasised that there is no correlation between the composition at which the surface tension is stationary and that at which the total vapour pressure is stationary. Another subject treated exhaustively is the possibility of variations of the amounts of bulk phases and surfaces without any variation of their nature. In fact the exhaustiveness seems rather exaggerated when a mathematical proof is produced that for a variation of the amounts of bulk phases without any variation of their compositions it is essential that there be more than one phase!

There are about 400 formulæ all seemingly correct and all logically deduced. The monograph provides excellent practice for anyone wishing to master the more intricate application of Gibbs' methods to complicated systems.

In one of the few places where the author discusses experimental data he is less fortunate. Referring to Adam and Jessop's measurements of the surface tension of films of myristic acid on aqueous  $N/100$  hydrochloric acid, he suggests that these authors ought to have investigated whether there were not sufficient adsorption (presumably negative) of the hydrochloric acid to modify its bulk concentration. A consideration of the order of magnitude of adsorption tells us that an effect of the type suggested would require the ratio surface/volume to be magnified to the order of magnitude met in colloids or porous materials. It would be entirely negligible in Adam's trough. Furthermore such an effect, if present, would have shown itself in that the values obtained for the surface tension would have depended on the depth of liquid in the trough and the experimental results would have appeared unreproducible. As the discussion of these experiments was included for the express purpose of demonstrating the usefulness of the author's formulæ the choice was particularly unfortunate.

The general arrangement of both monographs gives the impression that the parts taken from the author's various papers have been thrown together without sufficient consideration of what would be their natural order. In view of this it is particularly unfortunate that there is no alphabetical index.

Considering the complicated symbols used there are remarkably few misprints in the text and formulæ, though they are rather numerous in the footnotes. The printing is admirable.

E. A. GUGGENHEIM.

# ZERO POINT ENERGY IN THE DETERMINATION OF THE STRUCTURE OF SOLIDS.

BY A. R. UBBELOHDE.

*Received 14th November, 1935.*

## I. Covalent and Ionic Linkages.

Substitution of one isotope for another in a solid chemical compound will lead to differences in the vibrational and rotational frequencies of the molecules, without in general changing the function expressing the potential energy of the solid in terms of its structure. Such substitutions will therefore only influence the structure in so far as this is affected by the vibrational and rotational energies of the molecules. The object of the present communication is to point out that the magnitude of the effects to be expected in certain cases should be sufficient to give valuable information on the structure of the solid.

In practice, appreciable differences in vibrational energy are only to be expected in the case of light isotopes, as in changes from deuterium to hydrogen, since the frequency is a function of the reduced mass  $\mu$ , where  $\frac{1}{\mu} = \frac{1}{m_A} + \frac{1}{m_H}$  or  $\frac{1}{m_D}$  and  $m_A$  is the mass of the other atom or atoms composing the solid. Rotational frequencies, which depend on the moments of inertia of the molecules, will likewise only show an appreciable difference for hydrogen and deuterium compounds, for which the effects to be expected may be summarised as follows:—

**Ionic Linkages.**—The only lattices in which hydrogen appears as one of the ions are the hydrides of the alkali metals and alkaline earths. These have high melting points, and on electrolysis the molten salt the hydrogen appears at the anode. Lithium hydride has a rock salt structure, the hydrogen playing the part of the chlorine ion; a comparison of LiH and LiD has shown quite an appreciable difference in the lattice dimensions<sup>1</sup>

For LiH  $a = 4.080 \pm 0.001$ .

For LiD  $a = 4.060 \pm 0.001$ .

It is important to determine whether this difference can be satisfactorily accounted for on grounds of the difference in thermal and null point energy of the two crystal lattices, or whether other factors have to be included. Neglecting atmospheric pressure, the equation of state of the solid may be written<sup>2</sup>

$$G(V) = YE,$$

<sup>1</sup> Zintl and Harder, *Z. Physik. Chem.*, 1935, 28B, 478.

<sup>2</sup> Debye, *Physik. Z.*, 1913, 14, 259.

where  $E$  is the energy content,

$$G(V) = V \frac{d}{dV} W(V)$$

$V$  is the volume,  $Y = \frac{-d \log \nu_m}{d \log V}$ , where  $W(V)$  expresses the potential energy of the crystal in terms of the volume.

For LiH,  $\nu_m$  can be calculated from the results of Günther.<sup>3</sup> Assuming the validity of Debye's expression for the specific heat,

$$\Theta_{\text{LiH}} = \frac{h\nu_m}{k} = 815^\circ \text{ K.}$$

For LiD, where the forces between the atoms are so far as is known identical with those for LiH, but the masses of the vibrating particles differ,

$$\frac{\nu_{\text{mLiH}}}{\nu_{\text{mLiD}}} = \sqrt{\frac{\mu_{\text{LiD}}}{\mu_{\text{LiH}}}} = \sqrt{\frac{16}{9}}$$

and

$$\Theta_{\text{LiD}} = 611^\circ \text{ K.}$$

From these two characteristic temperatures the energy content at  $293^\circ \text{ K.}$  is <sup>4</sup>

$$\text{For LiH} \quad E - E_0 = 544 \text{ cal./mole.}$$

$$\text{For LiD} \quad E - E_0 = 745 \text{ cal./mole.}$$

The values of  $E_0$  may be calculated assuming a continuous distribution of frequencies of the lattice, ending at  $\nu_m$ , with  $3N$  frequencies in all, as in Debye's theory, *i.e.*—

Number of vibrations between  $\nu$  and  $\nu + d\nu$  is

$$4\pi V \left[ \frac{1}{c_1^3} + \frac{2}{c_t^3} \right] \nu^2 d\nu$$

Also

$$3N = 4\pi V \left[ \frac{1}{c_1^3} + \frac{2}{c_t^3} \right] \frac{\nu_m^3}{3}$$

Thus, the number of vibrations between  $\nu$  and  $\nu + d\nu$  is  $\frac{9N}{\nu_m^3} \nu^2 d\nu$ , and the total zero point energy

$$\begin{aligned} E_0 &= \frac{9N}{\nu_m^3} \int_0^{\nu_m} \frac{h\nu}{2} \nu^2 d\nu \\ &= \frac{3}{8} N h \nu_m = \frac{3}{8} R \Theta \end{aligned}$$

$$\text{For LiH at } 293^\circ \text{ K.} \quad E = E_0 + 544 = 1820 + 544 = 2364 \text{ cal./mole.}$$

$$\text{For LiD} \quad E = E_0 + 745 = 1368 + 745 = 2113 \text{ cal./mole.}$$

It is clear that the fairly large difference of 452 cal in the zero point energy is already partly compensated at  $293^\circ \text{ K.}$  by the difference of 201 cal in thermal energy; for crystals with lower  $\Theta$  than lithium hydride this compensation is still more complete, and masks the effect of changing isotopes, except at lower temperatures.

Without knowing the values of  $Y$  and  $G(V)$ , it is still possible to obtain an estimate of whether this difference of 251 cal between LiH and LiD at  $293^\circ \text{ K.}$  can account for a difference of 0.020 Å in the lattice dimensions,

<sup>3</sup> *Ann. Physik.*, 1920, **63**, 476.

<sup>4</sup> *Cf. Landolt Bornstein*, Tab. 5th Ed. I., 705.

i.e., an expansion of  $0.02/4 = 5 \times 10^{-3}$  per unit length. The thermal expansion of the crystal is due to an increase in  $E$  with rise in temperature, and for a specific heat of about 8 cal/mole a difference of 250 cal corresponds approximately with  $30^\circ$  rise in temperature. If the coefficient of expansion of the crystal at room temperature were of the order  $5 \times 10^{-3}/30 = 1.7 \times 10^{-4}$ , the results would be consistent with the view that the only differences in the lattices arise from differences in vibrational energy content. There seems to be no direct measurement of the coefficient of expansion on record, but even potassium with a much lower melting-point has a coefficient of only  $0.8 \times 10^{-4}$ , so that the value calculated above is rather large. The Debye theory may only be a first order approximation for lithium hydride, however,<sup>2</sup> and a bigger actual difference of  $E$  would require a smaller coefficient of expansion to give the observed change of lattice dimensions on changing the isotopes.

**Organic Solids.**—Many organic solids are made up of complex molecules whose internal vibrations are almost completely independent of the vibrations of the molecules in the lattice; for such solids the Raman spectrum is practically the same as for the gas, and the heat of vaporisation is small compared with the bonding energies of the individual atoms in each molecule.

Unless the percentage of hydrogen is high, a change to deuterium will not make much difference to the mass of the whole molecule, and will hardly affect the lattice vibrations. Furthermore, the characteristic temperatures will be low, so that any difference in null point energy is practically compensated for by differences in thermal energy at ordinary temperatures. Unless the coefficient of expansion of the solid is abnormally high, the expansion of the lattice on change of isotopes due to the change in lattice vibrations will be small or negligible.

A much more important effect arises from the change in the distance of minimum approach of the molecules (van der Waals,  $b$ ). So long as the vibrations are simple harmonic, the mean positions in space of the atoms in each molecule remain unchanged, since the function expressing potential energy against separation is generally the same for two isotopes. Owing to the difference in mass the frequency of vibration will, however, differ, and so will the amplitude of oscillation, which corresponds with the difference in zero point energy and thermal energy of the bonds. If there is practically no interaction between the lattice vibrations and the internal vibrations of the molecules, it must be assumed that the minimum distance of approach is conditioned by the amplitude of these internal vibrations.

The magnitude of the change in  $b$  on changing from A—H to A—D at a single linkage may be estimated in the case of simple harmonic vibrations. Among the valency bonds, the frequencies AH/AD will be in the ratio  $\sqrt{\frac{\mu_{AD}}{\mu_{AH}}}$ . The energies for the linkages with H(<sub>1</sub>) and D(<sub>2</sub>) will be

$$E_1 = \frac{h\nu_1}{2} = 2\pi^2\mu_1a_1^2\nu_1^2$$

$$E_2 = \frac{h\nu_2}{2} = 2\pi^2\mu_2a_2^2\nu_2^2$$

$$\frac{a_1^2}{a_2^2} = \frac{\mu_2\nu_2^2}{\mu_1\nu_1^2}$$

<sup>2</sup> Cf. Blackman, *Proc. Roy. Soc.*, 1934, 148A, 365.

or, since

$$\nu \propto \frac{1}{\sqrt{\mu}}, \quad \frac{a_1}{a_2} = \left(\frac{\mu_2}{\mu_1}\right)^{\frac{1}{2}}$$

For valency vibrations of the C—H bonds

$$\frac{1}{\mu_1} = \frac{1}{12} + \frac{1}{1} = \frac{13}{12}, \quad \frac{1}{\mu_2} = \frac{7}{12}$$

$$\frac{\mu_2}{\mu_1} = \frac{13}{7}$$

and

$$a_1 = 1.168 a_2 \quad a_1 - a_2 = 0.14a_1$$

also

$$a_1 = \frac{1}{2\pi} \sqrt{\frac{h}{\mu\nu}} \approx \frac{10^{-8}}{\sqrt{\nu}} \text{ cms.}$$

Similar calculations apply to the O—H and N—H bonds, the frequency of the valency vibrations being in each case of the order  $3000 \text{ cm.}^{-1}$  and the difference in amplitude, or in distance of minimum approach, will be  $1.5 \times 10^{-10} \text{ cms.}$ , which should in some cases be detectable.

The characteristic temperature of these valency oscillations is about  $4000^\circ \text{ K.}$ , so that at ordinary temperatures only the zero point oscillation is of significance. For smaller frequencies the difference in amplitude is bigger. This applies particularly to deformation oscillations. Nevertheless, this difference will, in general, have much less influence on the structure of the solid, since a small change in the uncertainty of the valency angle is not of great influence on the neighbouring molecules. Similarly, rotational frequencies, which differ on account of differences in moment of inertia, will only lead to differences of structure in the neighbourhood of transition points, due to molecules such as  $\text{NH}_4^+$  or  $\text{ND}_4^+$  rotating freely in the crystal.

If the C—H bond is fixed in the crystal, however, the change in distance of minimum approach due to valency vibrations takes place along the valency bond, so that the expansion on changing isotopes should affect the different lattice parameters unequally. In certain cases this may lead to the location of the C—H bond in space. If the benzene molecule is flat, for example, the expansion on changing from  $\text{C}_6\text{D}_6$  to  $\text{C}_6\text{H}_6$  due to the above effect should be restricted to the planes in which the molecules are lying in the solid. In the liquid, the effect is averaged over all orientations of the molecules, but the ratio of densities  $\text{C}_6\text{D}_6/\text{C}_6\text{H}_6$  should still be somewhat greater than  $84/78 = 1.077$ , owing to the change in  $b$ . The only available data <sup>6</sup> for the liquid give a ratio at  $17.2^\circ$  of 1.085, which is in the expected direction, but owing to difficulties of purification this numerical value may have to be altered. (The  $\text{C}_6\text{D}_6$  was made by polymerisation of  $\text{C}_3\text{D}_2$ ).

A much larger difference has been observed between the molecular volumes of liquid hydrogen and deuterium. Using a thermodynamic calculation Clusius and Bartolome <sup>7</sup> find for the molecular volumes:—

$$\text{D}_2 (\text{M.P. } 18.66^\circ \text{ K}). \quad \text{H}_2 (\text{M.P. } 13.95^\circ \text{ K}).$$

Solid $20.4 \text{ c.c.}$	$23.25 \text{ c.c.}$	difference $13.7 \text{ percent.}$
Liquid $23.1 \text{ c.c.}$	$26.15 \text{ c.c.}$	„ $13.0$ „

<sup>6</sup> Clemo & McQuillen, *J.C.S.*, 1935, 1220.

<sup>7</sup> *Z. Electrochem.*, 1935, 41, 487.

As would be expected from the fact that  $H_2$  and  $D_2$  rotate freely in the solid near the melting-point, there is no appreciable difference in the per cent. change on melting. The authors ascribe the whole of the difference between  $D_2$  and  $H_2$  to a change of internal pressure resulting from the change in zero point energy, but since their value for the change in internal pressure is  $17.3 \text{ kg./cm.}^2$ , this would require for the compressibility of hydrogen the very high value  $8000 \cdot 10^{-6}$  per bar. The only experimental value<sup>8</sup> of  $2000 \times 10^{-6}$  per bar suggests that for liquid hydrogen and deuterium at least part of the volume change is due to a change in  $b$ , and the rest to internal pressure changes.

A difference in the minimum distance of approach of  $H_2O$  and  $D_2O$  has also been suggested as one explanation of the difference in association of the two liquids in dioxan.<sup>9</sup>

### Organic Solids Involving Hydrogen and Hydroxyl Bonds, etc.

When some of the linkages between the molecules in the lattice have a binding energy bigger than is due to van der Waals' forces, but smaller than covalent or ionic binding energies, it is no longer adequate to treat the vibrations of the lattice as independent of the internal vibrations of the bonds. At hydrogen or hydroxyl bonds<sup>10</sup> when the H atom is bound with approximately equal energy to two other atoms the change on substituting D requires more complicated analysis, but will in general be smaller than in either ionic lattices, or the organic solids discussed above. The only type studied so far is  $H_2O$  and  $D_2O$ ,<sup>11</sup> where the difference in lattice parameters does not exceed 0.1 per cent. at  $0^\circ \text{C}$ . Since the OH groups are certainly not end to end, however, a change in minimum distance of approach even if there were no hydroxyl bond would not be readily detectable.

### Summary.

The effect of change of isotopes on the structure of solids is discussed for ionic solids in conjunction with the equation of state of the solid, and for organic solids involving only covalent links in conjunction with the change in minimum distance of approach of the molecules. In some cases the effects should be quite large enough to give definite information on the structure. For ionic solids, the results can be correlated with the distribution of lattice vibrations. For organic solids, the change may lead to the location of C — H bonds in space in some cases.

# THE VISCOSITIES OF LIQUID MIXTURES.

By K. E. SPELLS, PH.D.

Received 26th November, 1935.

The measurements described here were undertaken with the object of attempting to correlate viscosity with other physical properties. As a subject for such an attempt, any liquid or solution with marked anomalies from the point of view of one property is particularly desirable. In this connection, solutions of isoamyl alcohol in benzene suggest themselves, for the dielectric constant of such solutions presents peculiar features, whose origin is unknown. If the molecular polarisation is plotted against the percentage of alcohol in a solution of isoamyl alcohol in the non-polar solvent benzene, then, according to Lange,<sup>1</sup> a curve is obtained showing two maxima.

It seemed possible that the graph of viscosity against concentration for the same solution would exhibit corresponding anomalies. All the curves obtained, however, both for isoamyl alcohol and for the solutions of other alcohols in benzene, were quite regular, so that at first the relationship sought did not appear to exist. Nevertheless, before arriving at any definite conclusion, several questions, which will be indicated later, and which will probably form the subject of a later paper, have still to be investigated.

The present paper deals chiefly with an attempt to obtain by a physical argument a mathematical expression to represent the variation of the viscosity of binary liquid mixtures with concentration, the mixtures discussed being not only those on which the measurements described here have been made, but those whose viscosities have been measured by other experimenters.

## Measurements.

It was desired in this series of experiments to detect small changes in viscosity with a high degree of accuracy. Special precautions, therefore, had to be taken to preserve the liquid in the viscometer from contamination, and to prevent errors due to evaporation. For these reasons, a viscometer with special features was constructed which allowed a reproducibility in the time of transpiration to within one part in 5000 for the dilute solutions in benzene of the various alcohols investigated, while the accuracy in the cases of more concentrated solutions (of higher viscosity) was only slightly inferior. The time of transpiration in the whole series of experiments varied from 250 secs. to 2000 secs. approximately. An account of this viscometer has been published already,<sup>2</sup> so the experimental work may be dealt with very briefly.

The thermostat used was of the usual electric relay type, and it was found to keep the temperature of the apparatus constant to within  $\pm 0.1^\circ$  C. Errors due to change of viscosity with temperature were then beyond the limits of detection.

The use of an Ostwald type viscometer necessitates measurements of the time of transpiration and density of both the liquid under consideration and of a standard liquid, benzene in the present case, of which, for purposes of calibration, the viscosity must be known. The values for benzene were

<sup>1</sup> L. Lange, *Z. Physik*, 1925, **33**, 169.

taken from the International Critical Tables. The Hagenbach-Couette kinetic energy correction never exceeded 1 part in 450 in these experiments, and was taken into account where necessary. The density measurements were made at the same temperature as the viscosity measurements and, for medium and high concentrations, with the actual solutions. For low concentrations, the densities were measured at concentration intervals of 3 per cent. and the required values obtained by interpolation. The percentage accuracy was greater than that attainable for the transpiration time.

### Purity of Materials.

Kahlbaum's "Cryst. Thiophene Free" benzene was used. In the first few experiments, the benzene was specially dried with sodium wire, but as the viscosity was found to be unaffected by this treatment it was discontinued. The *n*-propyl and tertiary butyl alcohols were both treated by refluxing over suitable drying agents and then fractionating. The refractive indices for the  $H_{\alpha}$  line of the hydrogen spectrum were used as a criterion of purity in all three cases. The two isoamyl alcohols,  $\alpha$ -ethyl propyl alcohol and  $\gamma$ -methyl *n*-butyl alcohol, were used without any further purification, since little appears to be known of their physical properties.

### Results of Measurements.

Measurements of the viscosities of solutions of *n*-propyl alcohol in benzene have been made already by Dunstan,<sup>4</sup> who found a minimum in the viscosity-concentration curve at about 5 per cent. Dunstan, however, did not obtain many points at low concentrations of alcohol in benzene, so experiments were made, taking a larger number of observations, to give a better idea of the form of the curve in the region of the minimum.

The results obtained with solutions in benzene of *n*-propyl alcohol at low concentrations have been published already in graphical form,<sup>5</sup> but the curve is reproduced here for convenience in Fig. 1.

This curve, together with those given for dilute solutions in benzene of the other alcohols investigated, gives an idea of the accuracy attainable with the form of viscometer used. At the temperature (22° C.) at which the measurements were made, the minimum viscosity is seen to occur at a concentration of 3.1 per cent. of *n*-propyl alcohol in benzene.

FIG. 1.—*N*-propyl alcohol in benzene—low concentrations.

<sup>4</sup> A. E. Dunstan, *J. Chem. Soc.*, 1905, 87, 11.

A few readings were taken at the higher concentrations, and the resultant curve over the whole range of concentration (see Fig. 2 (i)), is similar to that obtained by Dunstan.

The curves obtained for solutions of tertiary butyl alcohol in benzene are shown in Figs. 2 (ii) and 3, while the curves for solutions of the two isoamyl alcohols used, in the same solvent, are given in Figs. 4 and 5.

It will be observed that the curves for all the four different alcohols investigated are very similar in form. In each case there is a minimum value of viscosity, less than that of either component, occurring at a low concentration of alcohol in benzene, while each curve is sagged.

Examination of the curves for the isoamyl alcohols reveals no essential difference of behaviour from that observed in the cases of the *n*-propyl and tertiary butyl alcohols. On this evidence, therefore, there does not seem to be any simple connection between the molecular polarisation and the viscosity coefficient. Before reaching any final conclusion, however, one or two other possibilities have first to be investigated.

Lange, in her paper, is of the opinion that the two maxima she obtained in the graph of molecular polarisation-concentration of isoamyl alcohol in benzene were due to the presence of at least two isomers, the resultant

FIG. 2.

- (1) *N*-propyl alcohol in benzene—all concentrations.
- (2) Tertiary butyl alcohol in benzene—all concentrations.

curve being a superposition of two curves, each normal, with their maxima in different positions. Therefore there may still be a relation between molecular polarisation and viscosity, which is not disclosed because the

substances used in the present experiments were possibly much purer, and did not contain more than a trace of any other isomer.

There is, however, another method for the investigation of this question. Recent theoretical work by Andrade<sup>5</sup> on the subject of liquid viscosity has indicated that investigation of the rate of change of the viscosities of liquids with temperature may prove to be more fruitful in providing knowledge of a fundamental character than the method of comparing the viscosities of different liquids at any arbitrarily chosen temperature. The equation given by Andrade for the variation of the viscosity of a liquid with temperature is

FIG. 3.—Tertiary butyl alcohol in benzene—low concentrations.

$$\eta^{1/3} = Ae^{c/T} \quad (1)$$

where  $v$  is the specific volume,  $\eta$  the viscosity at temperature  $T$  absolute, and  $A$  and  $c$  constants to be chosen for a particular liquid. The constant  $c$  depends on that part of the potential energy of a molecule involved in the variation of the viscosity of a liquid with temperature (see original paper).<sup>6</sup>

It seemed possible, therefore, that the variation of  $c$  with the concentration of isoamyl alcohol in benzene might show the anomalies sought.

Measurements of the dielectric constants of solutions of alcohols in benzene are now being carried out in the Physics Department of University College by Mr. Hari Ram Sarna, with the object of comparing values of these constants and of the viscosities obtained with solutions made up from the same specimens. The effect of traces of moisture on the dielectric constants has been found by him to be very marked, and may have vitiated previous results.

### An Equation to Represent the Viscosity Variation of a Binary Liquid Mixture with the Concentration of the Components.

A number of empirical formulæ have been proposed by different workers to represent the variation of viscosity with concentration, but only a few of these make any claim to generality, while none, so far as is known to the writer, will fit curves of the type obtained with the solutions of the alcohols investigated here.

It was observed while the measurements given here were being made that the curves, both of viscosity and density, plotted against concentration are sagged; i.e., the viscosity and density at any given concentration are both less than the values which would be given by a linear law. In the case of the density this means that there must be an expansion on mixing the two components of the solution together. Now it is well known that when a liquid undergoes an expansion due to the release of a compression acting on it, this expansion is accompanied by a decrease in its viscosity. It seemed, therefore, of interest to investigate the possibility of there being any connection between the corresponding variations of density and viscosity of a given liquid mixture.

Several investigators have observed the converse phenomenon, that mixtures which exhibit a viscosity maximum also show a definite contraction. McLeod,<sup>6</sup> however, appears to be the only one to work out a mathematical formula based on this observation. Assuming that a linear law holds for mixtures of components which mix without volume change, and basing his arguments upon considerations of free space, he obtained the following formula, which he found satisfactory for certain mixtures:—

$$\eta = (\eta_1 v_1 + \eta_2 v_2)(0.100/0.100 - C)^{A_1 v_1 + A_2 v_2}$$

where  $\eta_1$  and  $\eta_2$  are the viscosities of two liquids present as volume fractions  $v_1$  and  $v_2$  in the mixture, 0.100 is an arbitrary average value chosen in the case of all substances for the free space of both components, and  $C$  is the contraction per unit volume deduced from the density of the mixture, while  $A_1$  and  $A_2$  are the arbitrary constants calculated from two sets of data for the mixture.

We now propose to deduce an expression for the viscosity of a mixture, not in terms of free space, but, by using an equation giving viscosity as a function of specific volume, directly in terms of its density. The same initial assumption is made here as in McLeod's attempt, i.e., that a perfect mixture undergoing no volume change on mixing would give a linear law for viscosity-concentration (the relation between the density and concentration, expressed as volume of solute per unit volume of mixture, being, of course, a straight line). There is no real theoretical

<sup>6</sup> D. B. McLeod, *Trans. Faraday Soc.*, 1923, 19, 17.

justification for this assumption, since the viscosity-concentration curve for an ideal mixture is not known, but it can be defended on general grounds.

To express the viscosity of a liquid as a function of its specific volume at constant temperature, Andrade's viscosity-temperature equation (1) is adapted. If the temperature  $T$  be constant, we may write:—

$$\eta = A(I/v)^{1/2} e^{\beta/v}$$

replacing  $c/T$  by the constant  $\beta$ .

Suppose, now, that  $\eta$  and  $\rho$  be the viscosity and density of a mixture of a given concentration; then, with suitable values of the constants, we have:—

[illegible]

Now if  $\rho$  could be altered to the value it would have had, if there had been no alteration of volume on mixing the components together, then, according to the above assumption,  $\eta$  should change to the value calculated from the linear law of viscosity-concentration.

Therefore, if  $\eta$  changes to  $\eta_1$  when  $\rho$  changes to  $\rho_1$ ,

where

$$\rho_1 = \rho_1 + r(\rho_2 - \rho_1),$$

and

$$\eta_4 = \eta_1 + r(\eta_3 - \eta_1),$$

$r$  being the concentration by volume of the liquid 2 in the mixture of component liquids 1 and 2, and the suffixes 1 and 2 referring to the appropriate components, then we should have also:—

$$\eta_1 = \Delta p_1 / c^{sp_1} . \quad . \quad . \quad . \quad . \quad (3)$$

Dividing (2) by (3), we have : -

$$\eta = \eta_1(\rho/\rho_1)^{1/2} e^{B(\rho-\rho_1)} \quad (4)$$

giving the viscosity of the mixture in terms of its density  $\rho$ , the concentration  $r$ , and the viscosities and densities of the components 1 and 2, after choosing a suitable value for  $\beta$ .  $\beta$ , from its origin, should depend upon the composition of the liquid in question, whether a mixture or not; and since the composition varies, in the case of a mixture, with the relative proportions of the components present,  $\beta$  should be a function of the concentration. Since, however, there is no way of predicting the variation of  $\beta$  with concentration, we have to make the further simplifying assumption that  $\beta$  is a constant for any particular mixture under investigation. At first sight  $\beta$  might appear calculable from viscosity temperature variation data at different concentrations, but actually this is not possible, since it is doubtful, owing to the somewhat artificial assumptions made in deducing (4), whether there is any simple relationship between  $\beta$  and  $c$ .

In order to find the values of  $\beta$  appropriate to any given mixture, values of  $\beta$  are first of all calculated at different concentrations by taking logs of both sides of (4), giving :—

$$\beta.M = \frac{\log_{10} \eta - \log_{10} \eta_1 + \frac{1}{2} (\log_{10} \rho_1 - \log_{10} \rho)}{\rho - \rho_1}$$

$M$  being the modulus of common logs.

A single value of  $\beta$  is then chosen to give the best agreement with observation over the whole range of concentration, bearing in mind that

a difference between the value chosen for  $\beta$  and the actual value calculated will have least effect where the deviation of the density-concentration curve from the linear is smallest.

In the following tables, which are self explanatory, the formula is shown tested first of all against the results obtained by the writer with the solutions in benzene of the particular alcohols investigated here. The formula was not used to fit the results obtained for *n*-propyl alcohol in benzene, since the differences between  $\rho$  and  $\rho_1$  were too small at most of the concentrations for the calculations to be made with any degree of certainty (*i.e.*, the graph of  $\rho$  against concentration was nearly linear). This seems to indicate that the relation between viscosity and concentration for a binary mixture is not necessarily linear when there is no change of volume on mixing the components, or, at least, that absence of change of volume on mixing is not the only criterion for a perfect mixture. It is interesting to observe, however, that, in the case of *n*-propyl alcohol in benzene, the maximum departure from linearity was much smaller (being only 26 per cent.) than in the cases of the other three alcohols.

In view of the fact that the formula deduced has but one constant, as against the two arbitrary constants of McLeod, the agreement between calculated and observed results for the alcohol-benzene mixtures, on which the measurements described here were made, seemed sufficiently good to justify the trial of (4) against results obtained by other observers.

It was decided therefore to make tests on some of the mixtures against which McLeod tried his two constant formulæ; these being particularly suitable for the purpose since they give results as different as possible from those obtained here, showing maxima instead of minima in the viscosity-concentration curve. Also, McLeod's equation appears to be the only one having any extensive application to mixtures.

Several of the mixtures studied by McLeod have been selected at random, and equation (4) has been fitted to their viscosity-concentration curves. As may be seen from the tables, the single-constant expression deduced here is reasonably successful when considered in the light of what has been accomplished so far in this direction. In general it may be claimed that it fits the facts nearly as well as the two-constant expression of McLeod.

In one case, the fit has been improved by assuming that  $\beta$  varies linearly with concentration  $r$  \* according to the relation

$$\beta = \beta_1 r + \beta_2 (1 - r),$$

equation (4) then becoming an equation with two arbitrary constants:—

$$\eta = \eta_1 \left( \frac{\rho}{\rho_1} \right)^{\frac{1}{2}} e^{\{\beta_1 r + \beta_2 (1-r)\}(\rho - \rho_1)} \quad . \quad . \quad . \quad (4')$$

#### Acetic Acid and Water (15° C.).

\* To conform with McLeod's work, the calculations have been performed with  $r$  expressed as concentration by weight in Tables V., VI., and VII.

A better fit could certainly be obtained in the cases of most of the mixtures investigated by the introduction of a second arbitrary constant in this manner. This is to be expected, since, as has been mentioned,  $\beta$  should vary with concentration, but the assumption of a linear variation has no theoretical support. In fact, in the only cases where  $(\rho - \rho_1)$  is determined with sufficient accuracy for smooth curves of  $\beta$ -concentration to be obtained, these curves show a distinct minimum. This suggests that  $\beta$  might be replaced more profitably by non-linear functions. It seems probable, then, that the nature of the variation of  $\beta$  with concentration for a particular mixture will depend upon certain properties of the components; but until it is known what these properties are, no useful purpose will be served by introducing additional complications in equation (4).

I should like to take this opportunity to express my thanks to Professor E. N. da C. Andrade for suggesting the original problem and for his continued interest and help throughout the course of this work. My thanks are also due to the Department of Scientific and Industrial Research for a grant extending over part of the time during which the work described here was being done.

### Summary.

Accurate measurements of the viscosities of solutions of four alcohols in benzene have been made.

In an attempt to correlate viscosity with the dielectric constant, the results obtained for the viscosities of the solutions of two isoamyl alcohols in benzene have been examined for anomalies corresponding to those obtained in the case of the dielectric constants. The curves of viscosity plotted against concentration do not exhibit any peculiarities, but, before reaching a conclusion, a new method, suggested here, of investigating the problem must be tried.

An equation with one arbitrary constant has been deduced to give the viscosity of a binary liquid mixture in terms of its density. This equation has been tested against the measurements given here, and also against results obtained by other workers.

## THE EXTINCTION COEFFICIENTS OF IODINE AND OTHER HALOGENS.

BY E. RABINOWITCH AND W. C. WOOD.

*Received 4th December, 1935.*

In order to extend the experiments on the photochemical equilibrium in halogens<sup>1</sup> to iodine, we required the knowledge of the extinction curve of iodine vapour. Despite the great number of investigations dealing with the spectrum and photochemical properties of gaseous iodine, its extinction was measured only once, by Vogt and Koenigsberger.<sup>2</sup> They used saturated vapour at 48° C. and 88° C., and over-

<sup>1</sup> E. Rabinowitch, H. L. Lehmann, *Trans. Faraday Soc.*, 1935, 31, 689.

<sup>2</sup> K. Vogt, J. Koenigsberger, *Z. Physik*, 1923, 13, 300.

heated vapour at 400° C. Bonhoeffer and Harteck<sup>3</sup> computed the extinction curve of iodine using the values found by Vogt and Koenigsberger at 88° C. Some of our experiments pointed to this curve being incorrect, or, at least, not applicable to iodine vapour at room temperature. The extinction coefficients seemed to be at least twice the values given by the curve. Referring to the original paper, we found that, by using the measurements at 48° C. extinction coefficients 2, 3 or even 6 times greater are obtained. Some of them appeared to us to be rather too high. We considered it therefore advisable to re-measure the whole extinction curve, using iodine vapour at room temperature.

### Extinction Curve of Iodine.

The experimental arrangement consisted of a 1000 c.p. pointolite lamp run on a 220 V. battery supply, a lens projecting an image of the incandescent plate into the centre of a quartz absorption cell 12 cm. long, and a second lens forming an image of the plate on the slit of a monochromator.

A Hilger VI spectrograph was used at first, with a selenium iron photocell (Electrocell) connected to a Zernicke galvanometer (Z3, sensitivity,  $1.5 \times 10^{-10}$  amps. per mm.). The photocell, with a slit in front of it, slid along a scale in the focal plane of the spectrograph. A violet filter (Wratten No. 39) was used in front of the slit for measurements below 5000 Å., in order to suppress scattered light.

In later experiments we were able to use a quartz double monochromator (Hilger D 129). The photocell was fixed behind its exit slit. The results obtained with both instruments were in good agreement.

FIG. 1.—Extinction-curves of iodine vapour.

<sup>3</sup> K. F. Bonhoeffer, P. Harteck, *Grundlagen der Photochemie*, 1933, p. 89.

Iodine vapour was introduced from a container kept at about  $19^{\circ}\text{C.}$ , into the thoroughly evacuated absorption cell, of which the temperature was about  $20^{\circ}\text{C.}$ , and the cell closed by a stopcock lubricated with phosphoric acid and graphite. The density was taken from the known vapour pressure curve of iodine,<sup>4</sup> and roughly controlled by means of a manometer filled with sulphuric acid. The intensity of light transmitted through the cell was measured at different wave-lengths, first with iodine vapour in the cell and then with the vapour removed by touching the wall with a piece of cotton wool soaked in liquid air. The operation required less than a minute and the light intensity of the lamp was sufficiently constant to make the results absolutely reproducible. The exactness of the measurements was between 20 per cent. at  $4300\text{ \AA}$  (where the absorption was less than 2 per cent.) and 2 per cent. at  $5000\text{ \AA}$  (where about 20 per cent. of light was absorbed in the cell). Curve A, Fig. 1, shows the measured values. The left-hand scale of ordinates corresponds to concentration measured in mols. per litre, the right-hand one to pressures in atmospheres at  $20^{\circ}\text{C.}$  Curves B and C in Fig. 1, are derived from the measurements of Vogt and Koenigsberger, the upper at  $48^{\circ}\text{C.}$ , the lower at  $88^{\circ}\text{C.}$  Confirming our expectations, the extinction curve of iodine at room temperature was found to lie between the two curves of Vogt and Koenigsberger, and nearer to the upper one.

### Dependence of the Extinction on Temperature.

We made no measurements at higher temperatures, and are therefore unable to say positively that one (or both) of the curves of Vogt and Koenigsberger are incorrect. The change of the extinction coefficient with temperature which is suggested by these curves is, however, a very unusual one; they are supposed to increase by about 30 per cent. between  $20^{\circ}\text{C.}$  and  $48^{\circ}\text{C.}$ , and then to decrease so rapidly that the values at  $88^{\circ}\text{C.}$  become three, or even six, times smaller than those at  $48^{\circ}\text{C.}$

The dependence of the extinction curve on temperature has been investigated by Gibson and Bayliss<sup>5</sup> in the case of chlorine. They found a gradual decrease in the height of the maximum (attaining — 30 per cent. at  $765^{\circ}\text{C.}$ ) accompanied by an increase in extinction on both sides further away from the maximum. This behaviour was quantitatively explained by Gibson, Rice and Bayliss<sup>6</sup> as being due to an excitation of the first vibrational level of the  $\text{Cl}_2$  molecule.

A similar flattening and broadening of the extinction curve with rising temperature was observed in bromine vapour by Ribaud,<sup>7</sup> and in iodine solution in hexane by Gr6h and Papp.<sup>8</sup> Their results must be explained in the same way—by an increase in the number of vibrating molecules of bromine and iodine. By virtue of the Franck-Condon principle, the absorption by the molecules in the first vibrational state produces two absorption maxima, situated on both sides of the main maximum due to the absorption by non-vibrating molecules. The existence of these two "humps" was shown by Gibson, Rice and Bayliss

<sup>4</sup> The reliability of this curve is very essential for the exactness of the extinction coefficients calculated in this paper. The data of J. P. Baxter, C. H. Hickey, and W. C. Holmes, *Trans. Amer. Chem. Soc.*, 1907, 29, 127, seem to be trustworthy, and agree well with those of F. Haber and F. Kerschbaum, *Z. Elektrochemie*, 1914, 20, 302. Our own measurements, however rough, showed no marked discrepancies with the data of Baxter, Hickey and Holmes.

<sup>5</sup> G. E. Gibson, N. S. Bayliss, *Physic. Rev.*, 1933, 44, 188.

<sup>6</sup> G. E. Gibson, O. K. Rice, N. S. Bayliss, *Physic. Rev.*, 1933, 44, 193.

<sup>7</sup> G. Ribaud, *Annales de physique*, 1919, 9, 11, 178.

<sup>8</sup> T. Gr6h, St. Papp, *Z. physik. Chem.*, 1930, 149A, 153.

by analysing the empirical extinction curve of chlorine. In the cases of bromine and of iodine, in which the vibrational quanta are smaller and more molecules are excited at room temperature, the humps on the red side of the maximum are easily recognisable on the curves (see the arrows in Figs. 1 and 3). In the case of iodine vapour (Fig. 1), the comparison with the band spectrum shown below, clearly indicates the hump as due to the superposition on the main band series of a second series, coming from the first vibrational state.

It is noteworthy that these humps appear in *solutions* of  $\text{Br}_2$  and  $\text{I}_2$  as well, showing that the vibrational quanta of these molecules are not strongly affected by dissolution in carbon tetrachloride and similar solvents.

### Effects of Concentration and Foreign Gases.

Vogt and Koenigsberger supposed that the differences between the extinction coefficients determined at different temperatures are due to differences in concentration rather than in temperature. One has to distinguish sharply between two regions in the spectrum of iodine. Below 4990 Å., the spectrum is continuous, and no deviations from Beer's law are expected theoretically (this prediction was confirmed, *e.g.*, by measurements with bromine). Above 4990 Å., the spectrum consists of lines (where the true extinction coefficients are very high) and intervals between them, where the extinction drops to zero. The extinction curve which one obtains experimentally in this region actually depends on concentration, thickness of the absorption cell and width of the slit. (With a very narrow slit, a zig-zag line must be obtained instead of a smooth curve.) With rising concentration of iodine, two effects occur simultaneously. *Firstly*, the *lowering* of the mean extinction coefficient with growing absorption, which is always observed when mean extinction coefficients are determined with non-monochromatic light covering a region where the true extinction coefficients are strongly variable. (To observe this, without the second effect, it is best to change the thickness of the absorption cell instead of changing the pressure.) *Secondly*, the *increase* in the mean extinction coefficient due to the broadening of the lines.<sup>(60)</sup> (To isolate this effect, it is best to add foreign gas instead of increasing the pressure of iodine itself.) The first effect falsifies the results, making the extinction curve dependent on special conditions of the experiment; the second effect restores the true shape of the extinction curve (at least so long as the influence of the foreign gas is confined to a change in the *shape* of the absorption lines and does not affect the absolute transition probability).

In order to obtain a curve showing correctly the average extinction coefficients in the band region, it is necessary to work with a sufficiently wide slit, covering a range containing several bands, and either use very low iodine pressures (or a correspondingly short light-path) or to add enough of the foreign gas to paralyse the effect of the higher iodine concentration. The correctness of the curve is ensured as soon as the extinctions in the centres of the lines become small enough to be representable by a linear instead of an exponential function.

<sup>(60)</sup> This effect was investigated by F. W. Loomis and H. O. Fuller, *Physical Review* [2], 1932, 39, 180, in iodine vapour, and by V. Kondratjew and L. Polak, *Z. Physik*, 1932, 76, 386, in bromine vapour.

In Fig. 1, the *dotted* curve in the region above 5000 Å. is the one we obtained by using a 0.5 mm. slit (covering regions from 50 to 100 Å. wide) with iodine at a pressure  $p = 0.157$  mm., and a light path  $d = 12$  cm. This is only one of the many curves which may be obtained in this region; even the strange shape of the upper curve in Fig. 1, with its minimum at 5300 Å. may be due to effects of this kind. The differences between this curve, and our curve at  $\lambda < 5000$  Å. cannot, however, be explained in this way, and still less can concentration effects account for the smallness of the extinction coefficients found by Vogt and Koenigsberger at 88° C.

Since it is difficult to measure very low absorptions exactly, the

FIG. 2.—The "limiting" extinction-curve of iodine.

between 5000 and 5500 Å., this causing the shifting of the maximum from 5000 to 5200 Å. The decrease in the pressure effect above 5500 Å. indicates that in this region the true extinction coefficients are not very high, even in the centres of the lines, and therefore no sensible increase in absorption is caused by broadening of the lines.

The increased absorption in the region 5000-5700 Å. is the cause of the fact that iodine vapour in an air-filled vessel appears more deeply coloured than vapour of the same pressure in an evacuated container.

It is noteworthy that the influence of the three gases helium, argon and air is the same—at least at the high pressure of 500 mm. used. This, together with the observation that no sensible increase in absorption

the easiest way to obtain the correct mean extinction curve of iodine in the band region is to use iodine vapour with inert foreign gases. Fig. 2 shows the results we obtained by adding 500 mm. of helium, argon or air to 0.157 mm. of iodine. According to expectations, the continuous region remains unaffected, but the mean extinction coefficients in the band region are considerably increased, especially

can be attained by a further increase in pressure, are indications that the extinction curve obtained in this way does not differ appreciably from the "limiting" curve corresponding to the ideal case of very low iodine pressure or complete line broadening.

The uppermost curve in Fig. 2, shows the extinction coefficients of iodine dissolved in carbon tetrachloride, according to Gillam and Morton.<sup>9</sup> The shape of the curve and the position of the maximum are the same as in the "limiting" curve for iodine vapour. The slight increase in the absolute values of the extinction coefficients will be discussed in the next section.

### Influence of Solvents on the Absorption Spectra of the Three Halogens.

In Fig. 3, the extinction curves of all three halogens in the gaseous state at room temperature<sup>10</sup> are compared with those of their solutions in carbon tetrachloride.<sup>11</sup> In the case of bromine, the greatest part of the spectrum (below 5100 Å.) and in the case of chlorine practically the whole of it are regions of continuous absorption. Accordingly, dissolution in a "neutral" solvent does not change the general shape of the

FIG. 3.—The extinction-curves of the three halogens in gas and solution.

extinction curves, nor the position of the maxima. The other effect of the solvent mentioned above is, however, clearly shown by these curves; The *absolute values* of the coefficients (*i.e.*, the corresponding transition probabilities) are increased by about 50 per cent. and more in the case of chlorine and up to 30 per cent. in the case of bromine; the corresponding effect in iodine is of the order of 15-20 per cent.<sup>11</sup>

<sup>9</sup> A. E. Gillam, R. A. Morton, *Proc. Roy. Soc.*, 1929, 124, 604.

<sup>10</sup> The data for chlorine gas are by Gibson and Bayliss,<sup>4</sup> for bromine by Ribaud.<sup>7</sup> We tested some points of this last curve and found the data of Ribaud confirmed.

<sup>11</sup> The curves for the solutions are those given by Gillam and Morton.<sup>9</sup> We use them because these authors give data for all three halogens. If the curves given by Gróh and Papp,<sup>8</sup> or O. S. Walker, *Trans. Faraday Soc.*, 1935, 31, 1435, for I<sub>2</sub> in CCl<sub>4</sub> are used instead of the curve by Gillam and Morton, the differences between the gas curve and the solution curve for I<sub>2</sub> become still smaller. It is deplorable that the extinction curves for I<sub>2</sub> solutions given in Landolt Börnstein's *Physikalisch Chemische Tabellen*, 5th edition, Vol. II., p. 894, are in error by a factor 10. Together with the wrong curve for the I<sub>2</sub> vapour they lead us to the belief that the extinction of iodine in solution is 50 times greater than that of iodine vapour whereas in truth they are nearly identical.

The explanation of this effect must be sought in the nature of the electronic transitions involved. They are of the "intercombination" type  $^1\Sigma \rightarrow ^3\Pi$ . Transitions involving a change of multiplicity are not allowed in very light atoms and molecules and become gradually easier with increasing atomic weight, due to a stronger interaction between spin and orbital momentum (e.g., a complete absence of intercombination lines in the spectrum of helium and the high intensity of the well-known resonance line 2536 Å. of mercury). This rule explains the increase in the absolute intensity of the absorption bands of the halogens in the series  $\text{Cl}_2$ ,  $\text{Br}_2$ ,  $\text{I}_2$  (the maximum values of  $\epsilon$  being 90, 160 and 740 respectively). The same cause must be responsible for the action of the solvent on the spectra of these three halogens. The electric fields of the surrounding molecules weaken the selection rules—an influence which is known from the appearance of many "prohibited" lines in the Stark effect of atomic spectra. This influence is strongest with chlorine, and becomes very weak in iodine, where the selection rule is already made ineffective by the interaction of spin and orbital momentum in the molecule itself.

### Summary.

(a) The extinction coefficients of iodine vapour at room temperature are measured between 4300 and 6200 Å. They are found to be 2 to 6 times greater than the values generally in use.

(b) The influence of temperature upon the extinction is discussed. Small humps observed on the extinction curves of bromine and iodine are shown to be due to absorption by vibrating molecules.

(c) The influence of the density is discussed. It is shown that the correct mean extinction curve in the band region can be obtained either by using a very low iodine pressure or—more conveniently—by adding an inert gas. Measurements are made with helium, argon and air, at 500 mm. The absorption in the continuous part of the spectrum is found to remain unaffected by the foreign gas, but the mean extinction coefficients in the band regions are considerably increased. The "limiting" extinction curve of iodine vapour obtained in this way has a maximum at 5200 Å., and a shape resembling that of the extinction curve of iodine dissolved in carbon tetrachloride.

(d) The influence of the solvent upon the extinctions of the three halogens is compared. The extinction coefficients are appreciably increased by dissolution, especially in the cases of  $\text{Cl}_2$  and  $\text{Br}_2$ . This is explained as being due to a molecular Stark effect enhancing the probability of the singlet-triplet intercombination, especially in light atoms.

We sincerely thank Professor F. G. Donnan, F.R.S., for his interest in this work, and Dr. O. Walker for valuable discussions.

# PROPERTIES OF ILLUMINATED IODINE SOLUTIONS. I. PHOTOCHEMICAL DISSOCIATION OF IODINE MOLECULES IN SOLUTION.

BY E. RABINOWITCH AND W. C. WOOD.

*Received 4th December, 1935.*

In this paper experiments will be described the purpose of which was to obtain direct evidence of the primary photochemical process in solutions of halogens. The experiments consisted in measurements of the change in the concentration of iodine-molecules in strongly illuminated solutions.<sup>1</sup>

## Experimental.

The arrangement was described in a previous paper,<sup>1</sup> and is shown schematically in Fig. 1. A rectangular glass cell A (20 × 100 mm.), con-

FIG. 1.—Scheme of the apparatus.

taining the iodine-solution, was substituted for the vacuum cell used in the previous work with gases. Automatic carbon arc (25 amps) was used for illumination ("illuminating light," intensity  $L$ ). In cases where especially high light intensity was wanted, a 120 amps search-light with a 20-inch parabolic mirror was substituted. The change in the extinction-coefficient of the solution caused by illumination was measured by a photoelectric compensation device consisting of a 6V., 24W. lamp PL ("photo-cell light," intensity  $I$ ), and the two selenium iron photo-cells PC1 and PC2. The details can be found in the above-mentioned paper.

Previously, we used the apparatus with gases. Since in solutions the effect is much smaller, it was necessary to increase further the sensitivity of the method. By improving all conditions relevant to the mechanical and optical stability of the apparatus, and by replacing one of the photo-cells by a new one with higher internal resistance, we were able to measure intensity changes of the order of  $2 \times 10^{-4}$  (0.002 per cent.) instead of  $1 \times 10^{-4}$  attained in our previous work. This accuracy proved to be sufficient for the detection of the dissociation effect in solutions, thanks to favourable conditions: the thermal effects, which were the chief source of trouble in experiments with gases, cause much less trouble in liquids.

<sup>1</sup> The same effect was previously investigated in gaseous bromine, see E. Rabinowitch and H. L. Lehmann, *Trans. Faraday Soc.*, 1935, 31, 689.

Although their theoretical magnitude is not much smaller, the time necessary for the establishment of thermal equilibrium is considerably larger (of the order of 100-1000 secs.) because of the high heat capacity of the liquid. Since the readings are taken a few seconds after the beginning of the illumination, the thermal effects are practically avoided.

On the other hand, we encountered an unexpected difficulty in keeping the intensity of the photo-cell light constant with a liquid in the path of the beam. Besides the quick fluctuations of the photo-current of the order of 0.002 per cent. which are also observed in working with gases, and are probably due to slight variations in the lamp voltage, we observed slower "drifts," often changing the intensity by as much as 0.1 per cent. They are relatively weak with aqueous solutions, but especially strong

with carbon tetrachloride. This indicates that they are due to thermal convection currents in the liquid, the dependence of refractivity on temperature being especially strong in the case of  $\text{CCl}_4$ . We were obliged to eliminate them by the method used in the previous work, i.e., taking a great number (usually 60) single readings and averaging them. Fig. 2 shows the results of a typical set of measurements. It represents the successive readings of the galvanometer, taken alternatively with closed and opened shutter between the arc and the absorption cell. The effect for which we were searching is clearly recognizable, although superimposed on

FIG. 2.—The dissociation-effect in iodine solution. Points show the extinction of the solution in the dark, circles that during illumination.

quick fluctuations of the current as well as on a slow drift. The total photo-current in this particular experiment was  $2 \times 10^{-4}$  amps, its variations due to the dissociation effect were about  $3 \times 10^{-10}$  amps (0.015 per cent.) and the drift over 5 mins. about 0.15 per cent.

### Results.

Experiments were made with iodine dissolved in  $\text{CCl}_4$ ,  $\text{C}_6\text{H}_{14}$ ,  $\text{CS}_2$ ,  $\text{CH}_3\text{OH}$  and  $\text{H}_2\text{O}$ , and with bromine in  $\text{CCl}_4$ . Only the solutions of iodine in carbon tetrachloride and hexane gave the "positive" effect shown in Fig. 2. In all the other solutions a "negative" effect was observed

instead, *i.e.*, an increase in the extinction-coefficient during illumination. This negative effect will be dealt with in a separate paper. Here we are concerned with the positive effects in  $\text{CCl}_4$  and  $\text{C}_6\text{H}_{14}$  only.

The measurements give (a) the total intensity of the light falling upon the photo-cell  $I$ , and its change  $\Delta I$ , due to illumination; and (b) the intensity of the illuminating light  $L$  (measured by a thermophile-galvanometer system calibrated with a standard lamp). From the relative change of transmission,  $\frac{\Delta I}{I}$ , the relative change on the concentration of  $\text{I}_2$ -molecules,  $\Delta[\text{I}_2]/[\text{I}_2]$ , is calculated. Instead of the method described previously,<sup>1</sup> we now used the following relation:—

$$\frac{\Delta I}{I} = \frac{\Delta[\text{I}_2]}{[\text{I}_2]} c_{(\text{I}_2)} \bar{\epsilon}_I d \ln 10 \quad . \quad . \quad . \quad (1)$$

where  $d$  is the length of the cell,  $\bar{\epsilon}_I$  the mean extinction coefficient of the solution for the photo-cell light,  $c_{(\text{I}_2)}$  the concentration of iodine molecules in mols per litre (units used in defining  $\epsilon$ ), and  $[\text{I}_2]$ , the same in number of molecules per c.c. Relation (1) is exact for monochromatic light only. The photo-cell light was filtered through an infrared absorbing glass, a green filter (Wratten No. 55) and a  $\text{Cu}(\text{NO}_3)_2$  solution. The spectral region transmitted was 4900–5200 Å., and the mean extinction coefficient was  $\bar{\epsilon} = 736$ . (The maximum extinction coefficient of iodine in  $\text{CCl}_4$  is 890, at 5180 Å). It remained practically constant for absorptions between 10 per cent. and 85 per cent., thus justifying the use of relation (1).

The same approximation (use of a mean extinction coefficient  $\bar{\epsilon}_L$ ) was used for the calculation of  $N_{\text{h}}$ , the number of quanta absorbed per sec. in 1 c.c. of solution. Three sets of filters were used:—

Filters.	Spectral Region Transmitted.	Maximum at	$\bar{\epsilon}_L$ ( $\pm 10$ per cent.).
1. 1 cm $\text{Cu}(\text{NO}_3)_2$ (25 per cent. sol.) + Wratten No. 32.	4000–5100	4000	325
2. 1 cm. $\text{Cu}(\text{NO}_3)_2$ (25 per cent.)	4000–5300	5000	625
3. Jena glass filter gg11 + 1 cm. $\text{Cu}(\text{NO}_3)_2$ diluted	5000–5800	5400	550

Because of the inconstancy and inhomogeneity of the light from the arc, the values of  $\bar{\epsilon}_L$  were determined by using the small lamp FL as light source (disregarding the fact that the intensity of distribution in the light of a glowing filament must be somewhat different from that in the light of a carbon arc, even in the narrow spectral regions concerned). The use of a mean coefficient  $\bar{\epsilon}_L$  was admissible, despite the wide range of the true  $\epsilon_L$  values involved (ranging from 100 at 4400 Å up to 890 at 5180 Å) because of the smallness of the total absorption across the cell (which was usually of the order of 10 per cent.).

The  $N_{\text{h}}$  values were calculated by means of the following formula:—

$$N_{\text{h}} = \frac{6.14 \times 10^3 \times 10^{-30}}{19.7 \times 10^{-17}} L \bar{\epsilon}_L C_{(\text{I}_2)} \times 1.13(1 + 2.3 \bar{\epsilon}_L C_{(\text{I}_2)}) \\ = 8.11 \times 10^{10} (1 + 2.3 \bar{\epsilon}_L C_{(\text{I}_2)}) L \bar{\lambda} \quad . \quad . \quad . \quad (2)$$

where  $6.14 \times 10^3$  is the calibration factor of the thermopile;  $L$  the intensity of the illuminating light (deflection of the galvanometer in cm.);  $1.13 \times (1 + 2.3 \bar{\epsilon}_L C_{(\text{I}_2)})$  are correction factors accounting for the reflexion losses and for the absorption between the middle and the back wall of the cell. The factor  $\bar{\lambda}/19.7 \times 10^{-17}$  ( $= \lambda/hc$ ) expresses the intensity by the number of quanta; the expression

$$6.14 \times 10^3 \times 1.13(1 + 2.3 \bar{\epsilon}_L C_{(\text{I}_2)}) L \bar{\lambda} / 19.7 \times 10^{-17}$$

represents thus the number of quanta passing a sq. cm. in the middle of the cell per second; on multiplying it by

$$\bar{\epsilon}_L C_{(\text{I}_2)} \ln 10 = 2.30 \bar{\epsilon}_L C_{(\text{I}_2)},$$

we obtain the number of quanta absorbed per second in 1 c.c.

# 550 PROPERTIES OF ILLUMINATED IODINE SOLUTIONS

Table I. gives the summary of the results. Column 6 shows the number of quanta absorbed, column 10 the corresponding change in the concentration of iodine molecules.

In order to make clear the meaning of the results, we first consider those obtained by variation of one independent variable only.

## Dependence of the Effect on Light Intensity.

In Table II. we compare the results obtained by variation of the number of quanta,  $N_{hp}$ , the concentration  $c(I_2)$ , and wave-length  $\lambda$  being kept constant.

TABLE II.—DEPENDENCE OF THE EFFECT ON LIGHT INTENSITY.

$$\frac{\Delta[I_2]}{[I_2]} = \text{const} \times N^x.$$

Exp.	$c(I_2) \times 10^3$ mols./l.	$N_{hv} \times 10^{15}$	$\frac{\Delta[I_2]}{[I_2]} \times 10^4$	$x$
111 ( $C_6H_{10}$ )	2.6	2.4	2.25	0.57
		1.0	1.37	
		4.6	1.32	
122 ( $C_6H_{10}$ )	5.9	2.1	0.87	0.54
		14.1	2.97	
		2.9	0.91	
123 ( $C_6H_{10}$ )	5.9	23.0	2.51	0.80
		7.9	1.00	

Table II. shows the law  $\frac{\Delta I_2}{I_2} \propto \text{const} \sqrt{N_{hv}}$  to be the best approximation. Exps. 122 and 123 were made with the 120 amps. search-light, giving a more powerful but much less constant and uniform illumination than the 25 amps. arc. used in exp. 111. The results are therefore less exact than those of exp. 111, which conforms exactly to the square root law.

#### Dependence of the Effect on Iodine Concentration.

Table III. shows the results obtained by changing the concentration  $C(I_2)$ , keeping  $L$  as constant as possible. The exponents  $y$  are in the neighbourhood of  $-0.5$ ; only exp. 111 suggests a proportionality with  $1/c(I_2)$  rather than with  $1/\sqrt{c(I_2)}$ .

TABLE III.—DEPENDENCE OF THE EFFECT ON IODINE CONCENTRATION.

$$\frac{\Delta[I_2]}{[I_2]} = \text{const} \times c(I_2)^y.$$

Exp.	$L$ (cm.)	$[I_2] \times 10^3$ mols./l.	$\Delta[I_2]/[I_2] \times 10^4$	$y$
101 ( $CCl_4$ )	14	2.2	0.37	-0.5
		8.8	0.45	
		11.0	0.41	
103 104 105 ( $CCl_4$ )	40	4.4	$\begin{Bmatrix} 1.23 \\ 1.33 \\ 1.05 \\ 1.32 \end{Bmatrix}$ mean 1.36	-0.7
		8.8	$\begin{Bmatrix} 1.18 \\ 0.65 \\ 0.69 \end{Bmatrix}$ Mean 0.84	
		13.2	$\begin{Bmatrix} 0.76 \\ 0.66 \end{Bmatrix}$ mean 0.71	
109 ( $C_6H_{10}$ )	38	6.4	1.32	-0.8
		12.8	0.77	
111 ( $C_6H_{10}$ )	40	2.6	2.25	-1.0
		4.3	1.32	
		9.6	0.76	

## Discussion.

We attribute the illumination effects observed in iodine solutions in carbon tetrachloride and hexane to a dissociation of iodine molecules into atoms. The stationary concentration of atoms must be equal to twice the number of  $I_2$  molecules disappeared :

$$[I] = 2\Delta[I_2]. \quad (3)$$

The values of  $[I]$  are calculated in column (11) of Table I. They are of the order of  $10^{-11}$  mols. per c.c. (corresponding to  $10^{-10}$  mols per litre).

The velocity with which the atoms are formed is :—

$$+ \frac{d[I]}{dt} = 2\gamma N_{hv} \quad (4)$$

The velocity of their recombination (assuming the simple mechanism  $I + I \rightarrow I_2$ ) is given by

$$- \frac{d[I]}{dt} = c[I_2], \quad (5)$$

and the stationary state by

$$[I] = \sqrt{\frac{2\gamma N_{hv}}{C}} \quad (6)$$

Formula (6) differs from formula (30) in our previous paper, (i) by the factor  $\gamma$  before  $N_{hv}$ , accounting for the possibility of the quantum yield of dissociation being  $< 1$ , due to the "primary recombination" discussed by Franck and Rabinowitch,<sup>2</sup> and (ii) by the disappearance of the factor  $[X]$  (concentration of foreign molecules acting as third bodies) because of the presence of the molecules of the solvent at each double collision between two iodine atoms in solution.

According to (6), the stationary concentration of iodine atoms must be proportional to  $\sqrt{N_{hv}}$ ; and since the absorption is (roughly) proportional to the concentration  $[I_2]$ , also to  $\sqrt{[I_2]}$ , the relative effect  $\frac{\Delta[I_2]}{[I_2]}$  must therefore be proportional to the square root of the light intensity  $\sqrt{L}$ , and to the inverse square root of concentration,  $1/\sqrt{[I_2]}$ . These predictions are in accordance with the results shown in Tables II. and III.

The velocity constant  $C$  cannot be calculated from the experiments, but only the quotient  $C/\gamma$ . The results are given in column (12) of Table I. The constancy of the results is not unsatisfactory, considering the extreme smallness of the effects measured. The mean values of  $C/\gamma$  are given in Table IV. :—

TABLE IV.—VELOCITY CONSTANTS OF THE RECOMBINATION OF I-ATOMS.

Solvent.	$C/\gamma$ .	$C'/\gamma$ .	$\gamma_{av}$ .
$C_6H_{14}$	$1.7 \times 10^{-10}$	$6.1 \times 10^{21}$	$2.4 \times 10^{-10}$
$CCl_4$	$2.3 \times 10^{-10}$	$8.2 \times 10^{21}$	$1.7 \times 10^{-10}$

$C$  is the velocity constant for concentrations measured in molecules per c.c.,  $C'$  the same for concentrations in mols per litre.

<sup>2</sup> J. Franck and E. Rabinowitch, *Trans. Faraday Soc.*, 1934, 30, 120.

The constants  $C/\gamma$  can be compared with that obtained previously for the recombination of bromine atoms in helium gas at atmospheric pressure. This was:—

$$C_1 \left( = \frac{C}{[\text{He}]} \right) = 7.5 \times 10^{-23}.$$

For atmospheric pressure,  $[\text{He}]$  is  $2.7 \times 10^{19}$ , and  $C$  becomes  $2 \times 10^{-13}$ ; whereas the corresponding constant in solution is of the order of  $10^{-10}$ , according to Table IV. (and assuming that  $\gamma$  is, if not equal to 1, at least of the order of 0.1 to 1). *The velocity of recombination of atoms in solution is thus about 500 times greater than in a gas at atmospheric pressure.* This result is in accordance with the assumption that triple collisions are necessary for the recombination in gas, and that practically each collision is a recombining one in solution.

*The dependence of the effect on light intensity, its dependence on iodine concentration and its absolute order of magnitude are thus all three in agreement with theory and support the explanation of the effect as being due to the simple mechanism.*

Something remains to be said about the coefficient  $\gamma$ . The simplest possible assumption is  $\gamma = 1$ . (This assumption cannot be *exactly* correct, because of the occurrence of the "primary recombination." The extent of this latter effect is however not yet known.) No clear trend of  $\gamma$  is revealed by comparing the effects observed in different spectral regions:—

$\bar{\lambda}$ :	4700	5000	5400 Å
$\overline{C/\gamma}$ in $\text{C}_6\text{H}_{14}$	1.75	1.9	1.2
in $\text{CCl}_4$	1.4	2.4	

In the second column about one-half, and in the third nearly the whole, of the absorbed quanta belong to the spectral region which is discontinuous in iodine vapour. We must thus assume, that in solution the quantum yield of dissociation in this region is the same as below 5000 Å, whereas in a sufficiently diluted gas this yield is  $\gamma = 1$  below and  $\gamma = 0$  above this limit. These results indicate, that dissociation of excited  $\text{I}_2$  molecules (and *not* dissipation of the excitation energy by collisions of the second kind) is the chief cause of the disappearance of the iodine fluorescence in solutions. The mechanism of dissociation must be the one discussed theoretically by Van Vleck<sup>3</sup> and illustrated by Fig. 3. The excited molecules in the state  $^3\Pi_0^+$  usually return by fluorescence into the ground state  $^1\Sigma$ . In the inhomogeneous electric field of the surrounding molecules, a transition from the state  $^3\Pi_0^+$  into the state  $^3\Pi_0^-$ , which is a "prohibited" one in the case of isolated molecules, becomes possible. Once in the state  $^3\Pi_0^-$ , the molecule becomes unstable and dissociates.

If the quantum yield  $\gamma$  is supposed to be  $= 1$  in solution throughout the absorption spectrum, then the values of  $C/\gamma$  in Table I. represent the actual velocity constants  $C$  of the recombination reaction, and we may use them for calculating the mean lifetime of the free atoms  $\tau$  (or their collision numbers  $s = 1/\tau$ , although this quantity has not much meaning for atoms which are supposed to recombine at their very first collision).

<sup>3</sup> J. H. van Vleck, *Physic. Rev.*, 1932, 40, 544.

In the last column of Table IV., the life periods  $\tau_0$  are calculated for  $t = 0^\circ \text{C.}$ , and a concentration corresponding to the pressure  $p = 1 \text{ atm.}$  in a gas. They are of the order of  $2 \times 10^{-10} \text{ sec.}$

With the aid of the usual kinetic formula for the calculation of the collision-number in gases, the mean time-interval between two collisions in a gas with a collision diameter  $\sigma = 5 \times 10^{-8} \text{ cm.}$  (a plausible value for the beginning of the interaction between two iodine atoms according to Fig. 3), is found to be :—

$$\tau_{0(\text{gas})} = 1.5 \times 10^{-10} \text{ secs.}$$

The practical identity between this value of  $\tau_{0(\text{gas})}$  and the values of  $\tau_{0(\text{solution})}$  calculated above suggests the following simple assumptions concerning the mechanism of the process under discussion :—

(1) *The quantum yield of dissociation of  $\text{I}_2$  molecules in solutions is in fact practically equal to unity throughout the absorption spectrum.*

(2) *The collision intervals of iodine atoms in solution are the same as calculated for iodine atoms in gas according to the kinetic theory. Each collision is a "recombining" one.*

This explanation would mean that "primary recombination," i.e., recombination of the atom-pair produced by absorption before its actual separation by diffusion—does not play an important rôle—at least in the case of  $\text{I}_2$ -solutions. The only important influence of the solvent upon the

FIG. 3.—Potential curves of the  $\text{I}_2$ -molecule according to van Vleck.

primary photo-chemical process consists in enabling a dissociation to occur in the spectral region where fluorescence is the only effect in sufficiently diluted gases.

This conclusion is, however, not at all a necessary one. An alternative explanation is made possible by a general assumption which will be discussed more fully elsewhere, and which postulates that : if, for two particles just in contact with each other in solution, the chance to separate without another collision is equal to  $1/n$ , then the average time-interval between separation and subsequent collision with another dissolved particle, is  $n$  times greater than the corresponding collision interval in a gas.

For the case in question, this assumption leads to the possibility of the following explanation :—

(I.a) The quantum yield of the dissociation of  $I_2$ -molecules is  $\gamma = \frac{1}{n} < 1$ .

(II.a) The mean life time of the free atoms  $\tau_{0(\text{solution})}$  is  $n$  times greater than the collision interval  $\tau_{0(\text{gas})}$  in a mono-atomic iodine gas.

The product  $\gamma\tau_{0(\text{solution})}$  remains in this way equal to  $\tau_{0(\text{gas})}$ .

The assumptions (I.a) and (II.a) would be improbable, if  $\gamma$  and  $\tau_0$  were two independent quantities. But, according to the above-mentioned general proposition, the same cause which decreases  $\gamma$  (by "primary recombination") increases the mean lifetime  $\tau_0$  in the same proportion. Further experiments are therefore necessary to ascertain the actual part played by the primary recombination in the photochemistry of iodine solutions.<sup>4</sup>

In the above-mentioned paper,<sup>2</sup> the dissipation of energy by collisions of the second kind with the solvent ( $I_2^* + CCl_4 \rightarrow I_2 + CCl_4$ ) was mentioned as a second possibility which may decrease the quantum yield of dissociation in solutions. For this loss of light-energy, however, no natural compensation by a prolonged life of free atoms can be expected. We may thus conclude, that the experimental results obtained with iodine in carbon tetrachloride and hexane, leaving open a possibility of energy-losses by primary recombination, show definitely the absence of important losses by energy-dissipation through second-kind collisions during the activated state of the  $I_2$ -molecule.

### Summary.

(a) By improving a photochemical compensation apparatus described previously, it was possible to measure extinction changes of the order of 0.002 per cent.

(b) By means of this apparatus, the reversible change of the extinction-coefficient of iodine-solutions under the influence of strong illumination was detected and measured.

(c) In the case of iodine solutions in carbon tetrachloride and hexane the effect consists in a decrease in the extinction coefficient, and is due to a dissociation of  $I_2$  molecules into atoms. Its dependence on light intensity and on  $I_2$ -concentration are in accordance with this explanation.

(d) The recombination velocity of iodine atoms in solution is about 1000 times greater than that of bromine atoms in helium at atmospheric pressure, in accordance with the assumption that triple collisions are necessary for recombination in gas, and that each collision is a recombining one in solution.

(e) The quantum yield of dissociation of  $I_2$ -molecules in solution is the same in the spectral region below 5000 Å, which is continuous, and above 5000 Å, which is a band region in  $I_2$  gas.

(f) The results can be explained in two ways:—

Either by the assumption that the quantum yield of  $I_2$  dissociation in solution is equal to 1, and the average lifetime of free atoms equal to the average collision interval in a monoatomic iodine-gas; or by the assumption that the quantum yield is  $1/n < 1$  (due to so-called "primary recombination") and the free lifetime of the atoms  $n$  times longer than the collision interval in the gas.

(g) Losses of energy by dissipation through collisions of the second kind between activated  $I_2$  molecules and molecules of the solvent do not occur to an appreciable extent.

<sup>4</sup> Any argument against primary recombination which is based on an estimation of the stationary concentration of free atoms in illuminated solutions is, according to this reasoning, fallacious. This applies, for instance, to the remarks made by Ogg on the occasion of the Symposium of Photochemistry held in San Francisco, 1935 (*Chemical Reviews*, 1935, 17, 423).

(h) In a number of solutions of  $I_2$  and  $Br_2$ , the extinction coefficients were found to *increase* reversibly during illumination. This "negative" effect will be dealt with separately.

Our sincere thanks are due to Professor F. G. Donnan, F.R.S., for his encouraging interest in this work and the hospitality he has generously shown us in the Sir William Ramsay Laboratories.

## QUANTITATIVE EXPERIMENTS ON EMULSIFICATION BY ULTRASONIC WAVES.

BY C. BONDY AND K. SÖLLNER.

*Received 24th December, 1935.*

Two previous papers <sup>1</sup> dealt with the mechanism of emulsification by ultrasonics in the systems: organic liquids in water and *vice versa*, and mercury in water and organic liquids. It appeared that the behaviour of organic liquids ("oils") had to be distinguished from that of mercury. In the case of oils emulsification was due to the collapse of cavitations produced by the ultrasonics at the interface of the two liquids. In that of mercury, drops of the other liquid driven into the mercury cause thin metal films to burst, thus forming small drops owing to the high interfacial tension.

In this paper some quantitative results are discussed concerning the nature of those emulsions, produced under different conditions.<sup>2</sup> Two points are of special interest: the amount dispersed under different conditions and the degree of dispersion.

A standard method of emulsifying is obvious in order to obtain reproducible and comparable results. Such a method is not easily realised; even when allowing for only a small degree of accuracy. The main difficulty is that the degree of emulsification depends on the mechanical vibration-energy, and the latter depends on several factors which are hard to control: a small difference in the thickness of the walls of the vessel used,<sup>3</sup> the relative positions of the vessel and the vibrating quartz

<sup>1</sup> C. Bondy and K. Söllner, *Trans. Farad. Soc.*, 1935, 31, 835, 843.

<sup>2</sup> Conf. preferably W. T. Richards, *J. Am. Chem. Soc.*, 1929, 51, 1724; H. B. Bull and K. Söllner, *Koll. Z.*, 1932, 60, 263; M. Reggiani, *C.R.*, 1933, 200, 123.

<sup>3</sup> The sound energy transmitted through a solid wall depends upon the thickness of the latter; cf. e.g., Lord Rayleigh, *Theory of Sound* (1896), Vol. II., p. 86; R. W. Boyle and G. B. Taylor, *Physic. Rev.*, 1926, 27, 518; R. W. Boyle, *Science Progress*, 1928, 75; E. Hiedemann and H. R. Asbach, *Physik. Z.*, 1933, 34, 734. But, as with test tubes the main part of the energy is transmitted by transverse vibrations of the glass walls and not by longitudinal waves in the latter. (Cf. also S. J. Sokoloff, *Elektr. Nachr.-Techn.*, 1929, 6, 454, and N. N. Malov and S. N. Rechevkin: *Hochfrequenztechn. u. Elektroak.*, 1932, 40, 134. The thickness of the glass is not so critical as might otherwise be expected. As thick walled tubes have a much smaller tendency than thinner walled ones to vibrate transversely, it is advisable to choose tubes of a moderate wall thickness, made from a high quality glass and well annealed, otherwise they are liable to break and thus to spoil the oilbath.

plate,<sup>4</sup> the position of this plate between the electrodes, etc., may cause marked differences. Further, it is impossible to perform the experiments under isothermal conditions; the temperature of the liquids rises more rapidly with increasing degree of dispersion, because heat is evolved, especially at interfaces.<sup>5</sup> This heat effect cannot be counterbalanced, even if the oilbath is cooled with streaming water. Yet, the formation and the properties of an emulsion depend upon temperature. Again, there is no satisfactory method available for direct measurement of the energy of high frequency sound waves. The only known factor is the amount of energy, characterised by the electric current, which enters the vibrating circuit.<sup>6</sup> Finally, the mechanical output may vary to a certain extent whilst the energy remains constant.

We do not claim that the experiments hereafter recorded have been carried out under, in any way, optimum conditions, but the conditions were those which in laboratory use proved to be good and convenient. The result—the first quantitative data to be published on emulsions prepared by ultrasonic waves—may nevertheless be of some interest, and they give suitable information on the general efficiency of this method.

Experiments have shown that the concentration of an emulsion produced, when maintaining the external conditions of the vibrating system as nearly the same as possible, did not vary<sup>7</sup> more than 20 per cent. This indicates how far the external conditions may be reproduced; yet this is only true, if the experiments are performed by the same experimenter who always dips the tubes in the same way into the oil fountain.

The experiments were carried out with 3 c.c. water, plus 3 c.c. of oil and 5 c.c. of liquid and 0.5 c.c. of Hg respectively, in test tubes of about 15 mm. internal diameter.

## 1. Water-Oil Systems.

### (a) Some Semi-Quantitative Data on Water-Oil and Oil-Water Emulsions.

As the main interest of this communication is not so much concerned with the nature of a great variety of emulsions, but mainly with the manner in which emulsions change with the conditions mentioned above, only semi-quantitative experiments with different substances were carried out; 3 c.c. of 1*N.* KCl solution (to exclude as far as possible differences due to a different charge of the different substances used in this series), and 3 c.c. of oil were irradiated in "thick-walled" test tubes of Monax glass, having an internal diameter of about 15 mm. The energy was only indicated by the strength of the current entering the secondary circuit (110 millamps. in this series). (Some further details relating to the energy question may be found in an earlier paper.<sup>8</sup>) The concentration of the emulsions was estimated from their opacity, a method which was proved to be satisfactory. The results are found in Table I.

The stability of the emulsions is moderate. The concentration is distinctly smaller after several hours. The droplets in both emulsions cream up or settle down respectively and unite with the coherent phases. The

<sup>8</sup> W. T. Richards, *loc. cit.*, also assumes the maximum error to be 20 per cent. With stabilised Hg emulsions our values were even less reproducible.

water phase is usually quite clear after standing over night, the oil phase in most cases, the viscosity playing an important rôle. With suitable stabilisers very concentrated and stable emulsions may be obtained.

Similarly, many organic liquids, or more correctly their saturated solutions, may be emulsified in each other.

### (b) Quantitative Measurements on Emulsions of Toluene in Water.

As a standard example for more thorough investigation, toluene-in-water emulsions was chosen, and the results obtained here may fairly accurately also hold for a great many other similar substances.

TABLE I—CONCENTRATION OF OIL—WATER AND WATER—OIL—EMULSIONS. ENERGY 110 MILLIAMPS. TIME OF IRRADIATION 1 MINUTE

In Table II. (a) the concentrations of the toluene-water emulsions obtained with varying time and energy of irradiation are recorded.

3 c.c. of toluene (pure, sulphur-free) and 3 c.c. of normal distilled water were irradiated in thick-walled (about 1 mm.) test tubes of Monax glass, having an internal diameter of about 15 mm. The concentration of the emulsion was calculated from its density, the latter being determined by means of a pycnometer. A fresh tube was used in every experiment. Hence, one may conclude from Table II. (a), to a certain extent, how far the results are reproducible; for instance, whether experiments performed with a constant energy show a regular trend. The energy was, as usual, only indicated by the strength of the current (in milliamps) entering the secondary circuit.

In pure emulsions (not containing emulsifiers) it was to be expected that the concentration would rapidly reach a limiting value: the rate of emulsification becoming equal to the rate of coagulation, i.e., the rate with

which the droplets unite to larger ones and coalesce with the bulk of the oil. This limiting value is 4.2-4.5 per cent. (per volume), when using high energies; with 80 milliamps it is reached in 3 minutes, with 115 milliamps in 30 seconds. Obviously, the rate of formation increases strongly with increasing energy; hence, it is surprising that the limiting value for 115 milliamps is not higher than that for 80 milliamps. We must conclude, from this fact, that the rate of coagulation also increases with rising energy. Below 50 milliamps the energy is not sufficient to cause emulsification. At 50 milliamps the limiting value is low.

With high energies (115 milliamps) the concentration decreases, when irradiating for a longer period. This is probably due to an effect caused by an increase of temperature, perhaps also to the degassing of the liquid. High temperature is disadvantageous for emulsifying, by ultrasonics (the collapse of the cavities being less pronounced), and moreover favours coagulation.

These "oils," e.g., toluene are mostly distinctly hydrophobic, and the emulsions which they form with water on shaking, without addition of

emulsifiers, so far as they are stable at all,\* are very dilute. Emulsions produced by ultrasonic waves are much more concentrated; evidently the factors causing dispersion are more powerful than in the case of shaking and stirring.

The degree of dispersion was determined in the following manner: a small amount of the emulsion was diluted with 5 to 10 times its volume of a 2 per cent gelatin solution. A drop of this stabilised emulsion was brought on to an object slide (having a cavity) and held for 30 minutes in a drying oven at 50° C.; the particles of the emulsion cream up and gather below the cover slide without undergoing coagulation. After the preparation had been examined under the microscope, a typical field was photographed (a water immersion lens and a magnification of 1000 being used). On the photograph about 300 droplets were counted and measured. Although this number may not be quite large enough for statistical purposes, it is adequate for our purpose.

Emulsions are generally characterised by the number of particles having a certain size. This method has its drawbacks, when the emulsions are very unevenly grained, as is the present case; it is not possible to see

\* Cf. e.g., W. Clayton, *The Theory of Emulsions and Their Technical Treatment*, 3rd edition, p. 5 (1935).

how the mass of the disperse phase is distributed among particles of different size, and this is actually of greater interest. The masses change in a ratio of 1 : 1000, if the ratio of the particle sizes changes from 1 : 10. We have therefore preferred masses to numbers.\* The results certainly are clearer, but they are represented less exactly; since we count statistically an insufficient number of particles, the rare appearance of specially large particles may be a serious cause of error.

Table III. (a) shows the distribution of the mass of particles (per cent. of total volume of disperse phase) among the particles of different size (diameter in  $\mu$ ).

Highly dispersed emulsions are formed, when the time of radiation is short and the energy small; under these conditions the concentration is low (*cf.* Table II. (a)), hence the tendency to coagulate is small. A long time of irradiation and a high energy favour coarser particles.

Dispersion becomes much more effective if an emulsifier is added (Table II. (b)). Experiments were performed under the same conditions with toluene and an aqueous solution of sodium oleate (1 per cent.). Since a slight excess of alkali favours the emulsifying action of a pure soap solution, the aqueous solution was prepared by adding somewhat more than the equivalent amount of NaOH to pure oleic acid.

The concentration of the emulsion increases with increasing time of irradiation, approaching the maximum value of 50 per cent. first rapidly, then more and more slowly. With an energy of 115 milliamps (and higher

\* The particles were counted and their masses calculated in the following way: the numbers counted referred to particles with a diameter below 1 $\mu$ , between 1 and 2 $\mu$ , between 2 and 3 $\mu$ , etc. When calculating the masses the average diameter of 1.5 $\mu$  was taken for the particles between 1 and 2 $\mu$ , 2.5 $\mu$  for those between 2 and 3, etc. To simplify the tables the relative masses of two neighbouring classes as to size were united. Sizes not mentioned in the tables were not observed.

values) toluene is emulsified in an equal volume of soap solution in less than 30 seconds. If more toluene is gradually added, it is also rapidly dispersed, until a concentration of about 75 per cent. is reached. On adding still more toluene, the emulsion breaks: a thick layer of hydrocarbon appears on the top of the aqueous phase. It is rather surprising that the limiting value reached in this way agrees so well with the maximum concentration, 74.04 per cent. calculated from Wa. Ostwald's<sup>10</sup> phase volume theory, although the premises of this theory are not fulfilled, the particles being neither of equal size nor undeformable.

A comparison of Tables III. (a) and (b) shows that the emulsifier favours a higher degree of dispersion: a very distinct maximum is found for particles with diameters between 2 and 4  $\mu$ ; 95-100 per cent. of all are below 9  $\mu$ . Evidently ultrasonics emulsify very efficiently; with simple emulsifying devices so finely grained emulsions could not be produced. It is of no avail to continue irradiating an emulsion already formed; the particles merely become somewhat coarser. Table III. (b) shows that this is also the case with stabilised emulsions. This seems to prove that the presence of stabilisers does not prevent these emulsions becoming coagulated by ultrasonics, whereas the protection by sodium oleate is so strong that the mere increase in concentration would not cause the droplets to unite.

\* Different glasses have been used as in the other experiments.

When discussing the mechanism of emulsification in a previous paper,<sup>1</sup> the influence of pressure was proved to be characteristic. Table IV. records the distribution of particle sizes for the samples irradiated at different pressures, the liquids being saturated with gas; the concentrations were as before.<sup>1</sup> The time of irradiation was 30 seconds, the energy 115 milliamps; 5 c.c. of toluene plus 5 c.c. of water were used; the test tube had a width of 2.5 cm. Stabilised systems could not be investigated in this way because spontaneous emulsification occurred, whilst the liquids were saturated with the gas.

The degree of dispersion shows two minima: one at very low pressures, one at about 2 atmospheres. This rather complicated behaviour may probably be explained when considering the mechanism of emulsification and the fact that in the same system both high concentration and coarse particles are usually favoured by similar conditions.

The emulsification of oils by cavitations produced by other means (*cf.* previous paper, p. 838), *i.e.*, by the collapse of steam bubbles, was also investigated as to degree of dispersion. An emulsion, prepared in this manner, stabilised by sodium oleate, was investigated as to particle distribution (*cf.* Table III. (c)).

<sup>10</sup> Wa. Ostwald, *Koll. Z.*, 1910, 6, 103; 1910, 7, 64; 1929, 47, 131.

This result may be compared with the first experiment in Table III. (b) (50 milliamps, time of radiation 3 minutes; cf. also Table II. (b)). With ultrasonics the maximum is obviously more distinct; the emulsion is more evenly, and also more finely grained.

## 2. Metal Emulsions.

Mercury and "oils" differ as to their mechanism of emulsification (cf. the two previous papers<sup>1</sup>). This difference is probably due to the high interfacial tension of mercury. Since fused metals also have high interfacial tensions, we may expect them quite generally to be emulsified by the same mechanism. This was confirmed with Wood's metal, tin, sodium and potassium.

Concentrated emulsions in aqueous and non-aqueous liquids may be prepared with *Wood's metal*. The regulus of the metal, solidified during irradiation, always contained marked amounts of enclosed liquid,<sup>2</sup> and its surface was covered with a large number of blisters. This is clear proof that dispersion is actually caused by the bursting of metal films covering

bubbles of the dispersion medium. Very finely grained emulsions are produced in bromo-naphthalene and tetrachloro-ethane; they contain a large amount of particles of colloidal size; when the coarser particles have settled, the fluid above them is a stable, brown colloidal solution. Under the ultramicroscope strongly scintillating particles are visible, as is frequently the case with colloidal metal solutions.

The *alkali metals* form concentrated emulsions in organic liquids such as paraffin oil and xylene. Those in paraffin oil have very intense colours: reddish violet in the case of sodium, bluish green in that of potassium (owing to oxidation these colours disappear in course of time).

*Mercury* is the most suitable metal for quantitative experiments, since it is easily purified, and is chemically fairly inert. Table V. (a) records the concentrations found with 0.5 c.c. of distilled mercury in 5 c.c. of 0.002 mol. sodium citrate solution.<sup>11</sup>

The limiting concentration is about 6 g. per litre; its absolute value is practically independent of the energy introduced, but the rate with which it is reached increases with increasing energy. With somewhat smaller energy (50 or 60 milliamps) the rate of emulsification is so low that no equilibrium can be reached within a reasonable time.

<sup>11</sup> H. B. Bull and K. Söllner, *loc. cit.*<sup>2</sup>

In order to determine the degree of dispersion the emulsion, just formed, was stabilised with lysalbinic acid and glycerol was added to minimise the Brownian movement, and was then photographed, after having sedimented entirely (Table VI. (a)).

These emulsions are more finely grained than oil emulsions, but the droplets sediment fairly rapidly owing to the high density of mercury. With increasing energy and time of irradiation they become coarser, even when the concentration remains unchanged.

Similar experiments were performed with solutions containing an emulsifier; the mercury was dispersed in a 0.05 per cent. solution of lysalbinic acid, a substance well known as a powerful stabiliser for metals. Tables 5(b) and 6(b).

It is rather surprising that the drops of the stabilised emulsion are distinctly coarser than those of the pure ones. This is probably due to the

following facts: large drops, if formed at all, are stabilised by the emulsifier, and are therefore more likely to survive in stabilised emulsions; in pure emulsions they have a stronger tendency to disappear, coalescing with the bulk of the mercury. This easily happens, for the majority of metal films break in the interior of the mercury,<sup>11</sup> when bubbles of the non-metallic solution are driven together; the drops are there very close to the bulk of the metal. Large drops are formed, when thick films disrupt.<sup>12</sup> So long as the external vibrational energy is small such thick films become spontaneously thinner, and only disrupt owing to the action of the interfacial tension. If, however, the vibrational energy is large, it will cause the disruption of thicker films. The stabiliser may also favour thicker films: the rate at which these become thinner will be smaller when the mercury moves between the two films of adsorbed stabiliser; the life of the thick film is longer, and hence it is more probable that it will be dispersed by the high vibrational energy.

<sup>11</sup> On theoretical grounds, N. Marinesco has also come to the conclusion that ultrasonics of high energy produce coarser emulsions than vibrations of lower energy. But as we are unable to agree with his assumptions on the mechanism of the formation of these metal films, we prefer not to discuss his calculations on the relationship of particle size and energy.

Here the Hg is always covered with a thick grey sediment, which grows with increasing time of irradiation. Although these stabilised emulsions settle out and become somewhat coarser in time, they are very stable, and may be readily redispersed by gentle shaking, even after several weeks. The non-stabilised emulsions of Hg in water coalesce much more quickly; after several hours the amount still dispersed is distinctly less, and after 24 hours only a small fraction of the dispersed Hg has failed to unite with the metal in bulk.

We compared the emulsification of *mercury* in a number of *organic liquids*. In all cases 0.5 c.c. of mercury and 5 c.c. of liquid were irradiated with 115 milliamps for 1 minute. The concentration determined under these conditions is generally already the limiting value found for sodium

citrate solution (*cf.* Table VIII.) and also for non-aqueous liquids, provided that their viscosity was not too high. In order to microphotograph and thus determine the degree of dispersion, the emulsions were mixed with viscous paraffin containing a small amount of rubber.

We make no mention of several liquids, because the concentration was too small to be determined: cyclo-hexane, petroleum ether, benzene, toluene, xylene, ether, acetone, chlorobenzene, carbon disulphide. These liquids also, however, can form unstable and not very concentrated emulsions, if exposed to ultrasonics at a temperature close to the melting point of mercury.

With viscous liquids, such as glycol, glycerol, benzyl alcohol, very concentrated emulsions are produced. In this respect, mercury differs markedly from the "oils." As regards the latter, a high viscosity of the

aqueous phase is most disadvantageous for emulsification (Table VIII.). The amount dispersed was only estimated approximately from the aspect of the emulsion, a method which, as mentioned above, has been proved to be

sufficiently trustworthy. Benzene serves as an example for all other organic liquids.

This dissimilarity shows again the distinction which is to be drawn with regard to the mechanism of emulsification: high viscosity tends to prevent the formation of cavities, and the consequent strong mechanical

effects when the cavities, if formed, collapse; hence oils are but feebly dispersed in highly viscous liquids, so long as they do not show a strong protecting action. In the case of mercury a high viscosity of the other

phase does not seriously interfere with the formation of thin mercury films and their disruption. Thus small drops of mercury may readily be produced and high viscosity favours the stability of the emulsion formed.

In the homologous series of the aliphatic alcohols the stability of the emulsion increases, when ascending the series. To a certain extent, the change observed when passing from one alcohol to the next recalls the variation known as Traube's rule. The distinctly stronger emulsification in bromine derivatives when compared with closely related chlorine compounds is remarkable: ethyl bromide producing a concentrated emulsion, butyl chloride a very poor one. A similar difference exists between bromo- and chloro-benzene. Probably some surface reaction in the case of the bromo-substituted compounds is the reason for this behaviour.

Table VII. shows further that—as in the case of stabilised and non-stabilised aqueous mercury emulsions—a high limiting concentration may frequently coincide with a low degree of dispersion.

In previous experiments it had been observed that these unprotected emulsions are in many cases markedly stabilised by gases. Some determinations of the limiting concentration and the degree of dispersion are shown in Table IX.

In aqueous emulsions the influence of air is very distinct: in absence of air the limiting value is much smaller, both in pure water and in citrate

solution. A stabiliser such as lysalbinic acid is, of course, more powerful than air. Again, the more stable emulsions are coarser. The influence of air does not at once appear so distinctly in organic liquids. The limiting value shortly after irradiation is not so much changed. The difference becomes more obvious in course of time, the drops in the air-free emulsion coalescing more quickly than in those containing air. Owing, probably, to this rapid coalescence, the air-free emulsions seem to be coarser (Table IX.).

Table X. also indicates quite generally the degree of stability of Hg-emulsions in organic liquids. In solvents with a higher emulsifying power and higher viscosity, the emulsions (although settling down) are usually somewhat stable; in liquids like methyl- or ethyl-alcohol the particles unite in the course of several hours with the Hg in bulk.

In the presence of rubber as a stabilising agent very concentrated and stable emulsions may be obtained in many organic liquids.

### Summary.

1. The concentration and the degree of dispersion were determined in emulsions produced by ultrasonic waves under different conditions of time and energy of irradiation; the investigation was extended to emulsions of

organic liquids in water and *vice versa*, and of mercury in water and organic liquids, both in the presence and in the absence of an emulsifying agent.

Our heartiest thanks are due to Professor H. Freundlich for his interest in this work. We are also greatly indebted to Professor F. G. Donnan, F.R.S., for his generous hospitality.

## NOTE ON THE DECOMPOSITION OF NITROGEN IODIDE.

BY W. E. GARNER AND W. E. LATCHEM.

*Received 20th December, 1935.*

The composition of nitrogen iodide, when prepared by the addition of iodine to concentrated ammonia solution,<sup>1</sup> is very probably  $\text{NI}_3 \cdot \text{NH}_3$ . According to these authors, it decomposes giving nitrogen, iodine, and ammonium iodide as products in the proportions given by the equation  $8\text{NH}_3\text{NI}_3 = 5\text{N}_2 + 6\text{NH}_4\text{I} + 9\text{I}_2$ , and Eggert has shown that it gives the same products whether it is decomposed in the dark, or under the action of light or by detonation. The dark reaction proceeds at a measurable rate at room temperature, 80 per cent. being decomposed in 24 hours. The substance appeared to be promising for investigations into the relationship between thermal decomposition and detonation, similar to those previously carried out on lead azide, lead styphnate, and mercury fulminate, in which cases measurements were made of the change in length of induction period with temperature, and the rate of the thermal decomposition immediately preceding detonation.<sup>2</sup>

Eggert states that it is possible to dry  $\text{NH}_3 \cdot \text{NI}_3$  in a cathode vacuum without appreciable loss of weight, but this we have found to be impossible with an iodide prepared by running 880 ammonia into iodine in potassium iodide. The dry iodide always detonated after a few minutes at pressures below  $2 \times 10^{-3}$  cm. at the temperatures  $-20^\circ - 20^\circ\text{C}$ . The detonation apparently occurred as soon as the solid became dry. This made it impossible to proceed with the measurement of induction periods but the occurrence of detonation under such conditions was a phenomenon which was in itself of sufficient interest to warrant investigation.

### Experimental.

Nitrogen iodide was made by running 10 c.c. of 880 ammonia into a few c.c. of 0.07 molar  $\text{I}_2$  in normal KI solution and the precipitate washed

<sup>1</sup> Chattaway and Orton, *Amer. Chem. J.* 1900, 24, 159; Eggert, *Z. Elektrochem.*, 1921, 27, 547.

free from potassium iodide with N/100 ammonium hydroxide. Usually 0.01 to 0.025 grams of nitrogen iodide were prepared at a time. The precipitate was transferred to a small glass filtering funnel containing a pad of asbestos at the bottom and the bulk of the water removed by suction with a water pump. The funnel containing the iodine was lowered into a pyrex bulb, 5.5 cm. in diameter and 10 cm. long by the spindle device (Garner and Gomm),<sup>2</sup> and the bulb evacuated through a carbon dioxide trap by means of a Hyvac and a mercury vapour pump. Phosphorus pentoxide was usually placed at the bottom of the bulb, to assist in the drying process. Detonation always occurred during the evacuation at pressures of the order of  $10^{-4}$  cm. On account of the well-known sensitivity of nitrogen iodide to a blow, the detonation might have been caused by the fall of small crystals from the side of the glass funnel on to the crystals below, so that it was necessary to eliminate this possibility. After washing the iodide on a filter paper, it was transferred on a spatula to a very flat bucket made of either glass or platinum and introduced into the reaction vessel in this form. The chance of falling particles was thereby

FIG. 1.

much reduced, but nevertheless detonation always occurred in a hard vacuum after an interval of time which varies with the temperature of the iodide. At 20° C. it was 25 minutes, at 10° C. 50 minutes, and at 1° C. 60 minutes. It was noted that detonation occurred at about the time when the solid became dry.

It was found possible to dry the iodide if the removal of water was carried out at pressures not lower than  $2 \times 10^{-3}$  cm., and having dried it in this way, to study the mode of its thermal decomposition. Approximately 0.01 gm. of iodide (slightly moist) was placed in a flat platinum bucket and dried over a layer of  $P_2O_5$  at a pressure of  $2 \times 10^{-3}$  cm., and the rate of evolution of nitrogen was measured on a McLeod gauge. Typical curves are given in Fig. 1 for experiments at -17° and -11° C. respectively. There was a quiescent period during which the increases of pressure were small and irregular, which was probably due to slight decomposition occurring while the solid was drying. After this period, the rate of evolution of gas accelerated, then became approximately constant for a time, and finally slowed down practically to a standstill, although a large fraction of the iodide was still intact.

During the reaction, the walls of the vessel gradually became browned by the products. The deposit was transferred to the trap and on analysis was shown to be mainly iodine, and contained but a trace of ammonia. The reaction was thus occurring in an atmosphere of iodine vapour which increases in density with time, and it was possible that the retardation of the reaction was due to this cause. To test this, the pressure was reduced to  $2 \times 10^{-3}$  cm., and after a few minutes which sufficed to remove the iodine, the decomposition began afresh. As before, the reaction again slows down after a time and can be accelerated again by the removal of the products from the reaction bulb. Usually 0.01 gm. iodide can be completely decomposed after two evacuations of the products. On the other hand, if the pressure was reduced below  $2 \times 10^{-3}$  cm., the residual iodide detonates after the lapse of a few minutes, just as it did during the drying process if the pressure fell too low.

The length of the quiescent period was irregular and probably depended on the amount of water present in the iodide at the beginning of the experiment. Also the pressure-time curves were not reproducible at any one temperature, so that quantitative investigation of the phenomena will prove a difficult matter.

It was noted that the total nitrogen liberated was always 40-60 per cent. lower if detonation occurred at the commencement of the reaction than for decomposition without detonation. Similar phenomena are usually observed when small amounts of explosive are detonated in vacuum, and are due probably to the scattering of small particles of solid.

### Conclusions.

Nitrogen iodide can be completely decomposed at  $-20^{\circ}\text{C}$ . and upwards without detonation occurring, if the pressure above the solid be kept above  $2 \times 10^{-3}$  cm. Under these conditions, the volatile products of the reaction accumulate around the solid and this prevents the reaction getting out of hand. The reaction may be brought practically to a standstill if the vapour pressure of the products becomes sufficiently high. Water also confers a certain measure of stability on nitrogen iodide.

In a hard vacuum, however, the water and the products of the reaction are so rapidly removed from the neighbourhood of the solid, that the reaction gets out of hand and detonation occurs.

The decomposition of nitrogen iodide has many of the features of a chain reaction and the above phenomena can be explained on this basis. In the absence of adsorbed water vapour or iodine, these chains have probably an infinite length, thus accounting for detonation. Iodine or water molecules adsorbed on the crystal surfaces are able to break the chains and so reduce the rate of reaction to measurable dimensions. This case is of interest because in the solid reactions hitherto investigated, reaction occurs more readily in the interface between the solid and its products than on the bare solid surface, whereas the reverse is true for nitrogen iodide. It is thus an example of a negative catalytic effect caused by the products. The instability of crystals of nitrogen iodide when the surfaces are free from adsorbed water or iodine probably accounts for its high sensitivity to shock, for fracture of the crystals produces momentarily surfaces free from adsorbed gases, and under such conditions it has been shown that the crystals detonate.

# THE BEHAVIOUR OF WATER HELD IN FINE-PORED MEDIA.

## *A Correction*

BY B. H. WILSDON, D. G. R. BONNELL AND MISS M. E. NOTTAGE.

*Received 17th January, 1936.*

We are indebted to Dr. R. K. Schofield of the Rothamsted Experimental Station for pointing out certain errors in our paper appearing under the above title.<sup>1</sup> These involve the indirect calculations of hydrostatic pressure from the published data of other workers plotted in Fig. 3.

In a recent paper,<sup>2</sup> Schofield uses the equation  $\Delta P_{\text{atm.}} = 0.09\Delta T$  to calculate the hydrostatic pressure to which a liquid held in a porous medium is subjected from the lowering of the freezing-point  $\Delta T$ . In the derivation of this relationship, it appears to be assumed that, on freezing, the ice separates at atmospheric pressure. The results of Bouyoucos and Parker quoted by us were calculated according to the formula

$$\frac{dp}{dT} = \frac{L}{T(v_1 - v_2)},$$

where  $L$  is the latent heat of fusion and  $v_1$  and  $v_2$  the specific volumes of water and ice respectively, on the assumption that the ice must be regarded as separating under the hydrostatic pressure of the liquid. This gives, however, a result of the opposite sign to that plotted by us. We find it difficult to accept Schofield's calculation, in which the volume change of the phases is ignored, for the reason that a positive pressure will usually be exerted by the ice on freezing. It must be admitted, however, that no alternative calculation which can take account of this condition is yet available.

Two other inaccuracies have also been detected: (i) In the curve derived from Szigeti's vapour pressure data the water content should be regarded as too high by 9.2 per cent. (ii) Owing to some ambiguity in Thomas's paper as to the actual temperature of experiment, and the corresponding true values of the vapour pressure of pure water, the derived values of the hydrostatic pressure at the highest water content should be 2.5 atmosphere; the values at lower water contents are only slightly affected.

The corrected data still show discrepancies and, although we realise that no strict comparisons can be made between the materials to which these calculations apply and those used in our own experiments they tend, in our opinion, to reinforce the direct evidence obtained by us for the existence of an anomaly in the behaviour of liquids in porous media, and emphasise the desirability of obtaining measurements for the free energy of liquids in porous media by independent methods, as pointed out by us in our original communication.<sup>3</sup>

# THE PHOTODECOMPOSITION OF IODOFORM AND OF THE ALKYL AND ALKYLENE IODIDES.

By K. E. GIBSON AND T. IREDALE.

*Received 1st April, 1935.*

Organic compounds containing iodine are, generally speaking, unstable in the presence of light, whether oxygen be dissolved in them or not.<sup>1, 2</sup> Iodine is the most obvious product of decomposition, and is accompanied by hydrocarbons, which are the results of secondary reactions. It is considered that the carbon-iodine linkage is affected by the absorbed light, the excited state which arises is thought to involve a repulsion between the two atoms similar to the case of hydrogen iodide.<sup>3, 4</sup> The absorption spectra of most of the gaseous alkyl iodides are continuous in the near ultra-violet region, and so also are the spectra of gaseous methylene iodide and iodoform.<sup>5</sup> One would expect the quantum efficiency for the decomposition of these substances to be at least unity. An approximation to this was found by one of us working with liquid ethyl iodide.<sup>2</sup> Later W. N. Wallace found a very small, almost immeasurable, quantum efficiency for the decomposition of gaseous methyl iodide. This result was not published, but others have recently confirmed it.<sup>6</sup> Work on these substances was continued, with interruptions, until the present time. We present some results we have obtained with iodides of the simpler type, especially iodoform, which has usually been submitted to a photochemical oxidation.<sup>7, 8</sup> No quantum efficiency for the simple decomposition process seems to have been determined.

## Experimental.

The source of radiation was a Hanovia mercury vapour lamp, working on the 240 A.C. 50 cycle circuit, with the aid of a step-down transformer. The output was remarkably steady, only very occasional fluctuations in intensity were observed. By means of an aperture in front of the lamp, quartz lenses, and a large screen with the necessary opening, an approximately parallel beam of light was obtained, which could be focussed to fit exactly the circular opening in front of the thermopile elements. The thermopile was a Moll, large surface type, used without any cover, and fitted with a rubber ring, blackened on the outside. The internal diameter of this ring was the same as the diameter of the opening in front of the thermoelements. The thermopile and photochemical cell were mounted on a board in front of the screen, permitting easy alignment and forward and lateral movements of the thermopile. A Moll galvanometer was employed in conjunction with the thermopile.

<sup>8</sup> Mukherji and Dhar, *J. physic. Chem.*, 1931, **35**, 1790.

**Calibration.**—The thermopile was calibrated with the aid of a Hefner lamp, certified by the Reichanstalt. We followed the method of Coblenz,<sup>9</sup> using a 40 mm. aperture, the whole operation being carried out in a blackened cupboard with a movable blackened screen between lamp and thermopile. Draughts were eliminated as much as possible. Instead of using variable heights of flame and plotting a curve as Coblenz suggests, we worked with a fixed height (40 mm.), and carried out a large number (over 70) separate measurements, using the mean of these results in all subsequent calculations. Using Coblenz's figure for the Hefner lamp ( $23 \times 10^{-6}$  gram-calories per sq. cm. per sec.) this came out to be  $3.42 \times 10^{-6}$  gram-calories per sq. cm. per sec. for 1 cm. deflection on the galvanometer scale 1 metre from the galvanometer. Pure re-distilled amyl acetate (Kahlbaum) was used in the Hefner lamp, but no correction was applied for carbon dioxide and water vapour in the atmosphere, as this correction seems a little uncertain. At the conclusion of our measurements we checked our procedure with the aid of the uranyl oxalate actinometer described by Leighton and Forbes.<sup>10</sup> With the stirred solution and radiation of wave-length 3130 Å., we obtained, at 15° C. a quantum efficiency of 0.568 for the oxalate decomposition, which agrees very well with Leighton and Forbes's figure.

**Filters.**—For light of wave-length 3650 and 3660 Å. in the mercury arc we used Winther's rosaniline hydrochloride (0.03 per cent.) filter, and for 3130 Å., Winther's filter containing potassium chromate and nitrosodimethylaniline. This latter filter admits a little 3020 Å. light, but the intensity of this is less than the 3130 intensity in the mercury arc, and no great error is incurred through taking the total light absorbed as having a wave-length of 3130 Å. Infra-red radiation was shut off (partly) by means of water filters.

**Photochemical Cell.**—This was about 5 cm. long, with plane quartz ends. A weighed quantity of the substance was introduced into it, and the solvent dissolved over in a current of carbon dioxide. Caps were then fitted, and the contents sealed. In certain cases, *e.g.*, iodoform, the distillation was carried out in the dark.

**Solvents.**—Owing to the low vapour pressure of many of these iodides, investigations of their photodecomposition had to be carried out in solution, in order to obtain sufficient concentration. Benzene was the principal solvent, but we also used ethyl alcohol. The objections to this latter solvent will be discussed later.

**Method.**—The difference in the galvanometer deflections for the light beam falling on the thermopile when the photo-cell contained only the solvent and when it contained the solution, was taken as a measure of the absorbed light energy. (A correction should be applied in a more round-about way for the amount of light reflected and absorbed by the quartz end plates, and many investigators have worked out formulæ for this correction, sometimes introducing assumptions as to the magnitude of certain absorption coefficients, etc., which were never properly verified. We do not think that its omission will sensibly affect our main considerations, because we checked our results with the aid of the uranyl oxalate actinometer.)

The decomposition was never allowed to proceed so far as to involve appreciable absorption of the light by the liberated iodine. The galvanometer deflections were carefully checked at the beginning and end of the decomposition. The liberated iodine was titrated with a very dilute solution of sodium thiosulphate, a similar amount of the undecomposed solution being used as a comparison. This method is quite accurate, because it can be checked against solutions of known iodine content. In some cases, *e.g.*, iodoform, the titration had to be carried out with carbon

<sup>9</sup> Coblenz, *Bur. Standards Bulletin*, 1914, 11, 87.

<sup>10</sup> Leighton and Forbes, *J. Amer. Chem. Soc.*, 1930, 52, 3139.

dioxide or hydrogen bubbled through the solution, as well as through the comparison solution.

**Purity of Materials.**—Thiophene free benzene was dried over calcium chloride and distilled. Absolute alcohol was distilled after standing over lime.

Iso-amyl iodide (Kahlbaum) was shaken with dilute sodium thio-sulphate to remove traces of iodine, washed with water, dried over anhydrous sodium sulphate, and several times distilled, finally under reduced pressure, and kept in a dark bottle over silver foil. Cetyl iodide was pared by Mr. C. McGregor of the Department of Organic Chemistry, and was re-crystallised from ethyl alcohol. The material was pure white, with no trace of decomposition. Methylene iodide was made from iodoform and sodium arsenite,<sup>11</sup> re-crystallised several times, and distilled under reduced pressure. The final product had still a faint yellow colour, probably due to traces of iodoform, but the light absorption due to this in dilute solution was negligible. Iodoform was obtained from a good commercial sample by re-crystallisation several times from alcohol, and had a sharp melting-point ( $120^{\circ}$ ). Tertiary-butyl iodide was made from tertiary butyl alcohol and constant boiling-point hydriodic acid.<sup>12</sup> The distillate was shaken with dilute sodium thiosulphate, water, dried, and distilled under reduced pressure. The iodide remained colourless if kept unexposed to light and air.

### Discussion.

The quantum yield in the photodecomposition of iodoform in benzene in the absence of oxygen appears to be unity, if the results in Table I. are to be accepted as reliable. The region  $3650 \text{ \AA.}$  occurs in the first absorption band (continuous) of iodoform, and  $3130 \text{ \AA.}$  in the second.

<sup>11</sup> *Organic Synthesis* (Adams), 1921, 1, 57.

<sup>12</sup> Norris, Watt and Thomas, *J. Amer. Chem. Soc.*, 1916, 38, 1071.

The two maxima in the iodoform absorption occur at about 3500 Å. and 2940 Å., a frequency difference of 5440  $\text{cm}^{-1}$ , which is a little too small for the energy of excitation ( $^3P_{-1} - ^3P_{-2}$ ) of the iodine atom (7600  $\text{cm}^{-1}$ ). Nevertheless, these maxima (with separations varying from 5600 to 7800  $\text{cm}^{-1}$ ) occur in the continuous absorption spectra of other polyiodides, and it is difficult to attribute them to anything else. It can certainly be accounted for by the varying slope of the potential curves for the upper, excited state, as previously shown.<sup>6</sup> We can assume that  $\text{CHI}_3$  dissociates in the first region into  $\text{CHI}_2$  and  $\text{I} (^3P_{-1})$ , and in the second into  $\text{CHI}_2$  and  $\text{I} (^3P_{-2})$ . The quantum yield need not be very different in the two processes, but there are more possibilities of secondary reactions in the second region, because the  $\text{I}$  atom possesses excess energy of 21,000 calories (per gram atom), and the yield may therefore increase, with decrease in wave-length of the absorbed light.

The quantum, yield of unity may be fortuitous, in that two distinct secondary effects may be operative: (i) deactivation by collision (even with unstable, "repulsion" states this is not impossible<sup>13</sup>); and (ii) secondary reactions of the products of decomposition. The one will tend to diminish the yield, the other, in most cases, to increase it. But if such effects are operating it is remarkable that the yield is not more greatly influenced by the concentration.<sup>14</sup>

In the presence of oxygen the quantum yield is much greater<sup>8</sup> and it varies very much with the solvent employed. It seems that solvents with low dielectric constant give the highest yields,<sup>15</sup> a state of affairs not easy to predict. The oxidation of the  $\text{CHI}_2$  radicle evidently initiates a chain reaction involving further  $\text{CHI}_3$  molecules, which is responsible for the photochemical after-effect.

The quantum yield in alcohol seems to be a little higher, but it is doubtful if these results are as reliable as those obtained with benzene as solvent. Iodine slowly reacts<sup>16</sup> with ethyl alcohol with formation of  $\text{HI}$ , and this would give with the liberated iodine a certain amount of the  $\text{I}_3$  ion. As this absorbs very strongly in the iodoform region, the apparent absorption of the light by the iodoform, as measured, may be too great. Moreover, the formation of the  $\text{HI}$  would tend to diminish the yield of iodine, so that on both accounts the apparent quantum yield should be lower than anticipated. That this is not the case points to some other factor, such as the possible reaction between  $\text{HI}$  and  $\text{CHI}_3$ , or the influence of the solvent on the secondary reaction. Altogether, it would be safer not to base too many conclusions on the results obtained with alcohol as solvent.

The results we have obtained with the other iodides point to some variation of the quantum yield with the structure of the molecule, although it is not easy to account for these variations in any simple way. (Table II.). It seems that the quantum yield increases in the order: (a) iso-amyl  $\rightarrow$  cetyl;<sup>17</sup> (b) methylene  $\rightarrow$  iodoform; and (c) iso-amyl  $\rightarrow$  tert-butyl; that is, there is an increase in the quantum yield with (a) increase in length of carbon chain; (b) further replacement of hydrogen

<sup>13</sup> Franck and Rabinowitsch, *Trans. Faraday Soc.*, 1934, **30**, 120.

<sup>14</sup> West and Paul (*Trans. Faraday Soc.*, 1932, **28**, 688) found with ethyl iodide that the yield was remarkably independent of the concentration.

<sup>15</sup> Winther, *Trans. Faraday Soc.*, 1926, **21**, 595.

<sup>16</sup> Batley, *ibid.*, 1928, **24**, 438.

<sup>17</sup> The results which one of us<sup>8</sup> obtained with ethyl iodide cannot be included here, as the liquid itself was used, the substance acting as its own solvent, wholly different from benzene.

by halogen; and (c) change of central carbon atom from primary to tertiary. These effects run parallel with the results of Hartel and Polanyi,<sup>18</sup> who investigated the reactivity of the sodium atom with the chlorides; the diminishing activation energies in their experiments correspond to the increasing quantum yields in ours.

Bates and Spence considered that the low quantum yield in the case of methyl iodide was due to the great stability of the  $\text{CH}_3$  radicle, and its ready recombination with the liberated I atom,  $\text{CH}_3 + \text{I} = \text{CH}_3\text{I}$ . (More generally  $\text{R} + \text{I} = \text{RI}$ .) The increase in quantum yield as the molecule is lengthened or its hydrogen replaced by halogen, etc., must then be due to the reactions (i)  $\text{R} + \text{R} = \text{RR}$  or  $\text{R}' + \text{R}''$  ( $\text{R}' =$  saturated hydrocarbon,  $\text{R}'' =$  unsaturated (olefine) hydrocarbon), and (ii)

taking place more readily than (iii)  $\text{R} + \text{I} = \text{RI}$ . This might be compared with the Hartel and Polanyi results, because the reaction

like the reaction  $\text{Na} + \text{RI} = \text{NaI} + \text{R}$  is dependent on an activation energy which becomes smaller, when among other things, the length of the molecule (carbon chain) increases, or the hydrogen is replaced by halogen, etc. It is easy to speculate on these matters and to draw comparisons, but other possibilities may exist which should not be ignored. It is only assumed (mainly from the absorption spectrum and absence of fluorescence) that a molecule like  $\text{CH}_3\text{I}$  dissociates spontaneously on light absorption. But a polyatomic molecule, as distinct from a diatomic molecule, may have other ways of disposing of its kinetic energy of separation, due to its greater number of degrees of freedom. If the  $\text{CH}_3$  radicle is formed it should be capable of reaction. But Bates and Spence found that the addition of hydrogen to the photochemically decomposing  $\text{CH}_3\text{I}$  does not influence the yield, because the collision efficiency of the reaction  $\text{CH}_3 + \text{H}_2 = \text{CH}_4 + \text{H}$  compared with  $\text{CH}_3 + \text{I} = \text{CH}_3\text{I}$  is relatively very small.<sup>19</sup> This matter surely needs further investigation.

<sup>18</sup> Hartel, Meer and Polanyi, *Z. physik. Chem.*, 1932, 19B, 139.

<sup>19</sup> Hartel and Polanyi, *ibid.*, 1930, 11, 97.

Experiments are now being carried out in this laboratory on the photo-decomposition of mixtures of  $\text{CH}_3\text{I}$  and  $\text{HI}$ , where the  $\text{CH}_3$  radicle, if it is formed, will certainly react with the  $\text{HI}$ .

### Summary.

The quantum yield in the photodecomposition of iodoform in benzene in the absence of oxygen is not greater than unity. The different quantum yields for other iodides have been discussed, and some explanations advanced for the variations.

One of us (K. E. G.) is indebted to the University of Sydney for a Science Research Scholarship enabling him to collaborate in this work.

## DIFFUSION POTENTIALS AND MOBILITIES OF IONISED GELATIN. PART II. NEUTRAL AND ALKALINE SOLUTIONS.

BY DR. E. B. R. PRIDEAUX (*Nottingham*).

*Received 27th January, 1936.*

In a previous paper,<sup>1</sup> diffusion potentials of gelatin chloride were determined in solutions of about  $p_{\text{H}}3$ , against solutions of potassium chloride which had been equalised as far as possible, both in salt concentration and in  $p_{\text{H}}$ . Mobilities of the gelatin kation  $\text{G}^+$  were calculated from these results, which included a few in neutral solutions. The work has now been extended to neutral and alkaline solutions of potassium gelatinate using similar experimental methods.

An important investigation on this subject is that of Ferguson and Schluchter,<sup>2</sup> who determined the potentials of combinations with and without diffusion:

The difference of (1) and (2) gives the diffusion potentials  $E_d$ , which were set up as standing and flowing junctions by manipulating taps in the tubes which connected the two solutions. Sodium hydroxide solutions at concentrations  $c = 0.0137, 0.0505$  and  $0.0895 \text{ N}$ , were treated with gelatin until there was no change in potential, at which point the activity of  $\text{OH}'$  in the gelatin solution had become constant:

$$\text{i.e.} \quad E = \frac{RT}{F} \log \frac{a_{(\text{OH})_h}}{a_{(\text{OH})_l}} = \text{constant.}$$

A combination with amalgam electrodes:

<sup>1</sup> *Faraday Trans.*, 1935, **31**, I., 349.

<sup>2</sup> *J. Gen. Physiol.*, 1931-32, **15**, 463.

gave potentials which hardly changed at all with change of  $x$ , showing that  $a_{Na^+}$  is hardly affected by the substitution of gelatinate by hydroxyl ion. In the present work, this has also been assumed to be true for potassium gelatinate and potassium chloride. When the  $x/E$  curves of combinations (1) and (2) become parallel, *i.e.* the diffusion potentials were constant, it was assumed that the alkali was saturated with gelatin. In the 0.0137 *N* solutions this occurred between 20 and 25 g. of gelatin, *i.e.* within the limits 6.85 and 5.48 c.c. of *N*/10 alkali to 1 g. of gelatin. Below these limits alkali is completely combined.

### Saturation Capacities for Alkali.

As the amounts of gelatin " $x$ " in Ferguson and Schluchter's experiments were increased, the equivalents of gelatin increased and reached a nearly constant value of 1560 in the 0.0505 and 0.0895 *N* alkali. This holds for solutions containing from 2 to 6 per cent. of gelatin. The 1.0 per cent. solutions have a rather greater saturation capacity, requiring 7.8 c.c. of *N*/10 alkali to 1 g. of gelatin, which corresponds to an equivalent of 1280. By conductimetric titrations, Pauli and Safrin<sup>3</sup> find 7.3 c.c. and an equivalent of 1370 for ordinary gelatin, and 5.3 c.c., equivalent 1890 for a sample purified by electroanalysis, which, according to the authors, had had some  $G^*$  and  $G'$  forms, *i.e.* the most dissociated groups, removed by this treatment. The conductivity method was also used by Stearn,<sup>4</sup> who finds 7.58 to 7.35 c.c.; equivalent 1320 to 1360.

### Mobility of Gelatin in Concentrated Solutions.

In their calculations, Ferguson and Schluchter have treated the gelatin ion as univalent, *i.e.* they consider the motion per equivalent of negatively charged gelatin, and apply the simplified equation:

$$E_d = \frac{RT}{F} \ln \frac{u + v_1}{u + v_2}$$

Values of 0, 20, 40 were assigned to the mobilities of the gelatin anion  $v_1$  (really  $Fv_1$ ), and it was found that  $v_1 = 20$  agreed most closely with the experimental results.

It may be remarked that in these experiments, the maximum amounts of gelatin added gave solutions of gelatin saturated with alkali, containing, *e.g.* 7.7 and 7.4 c.c. of *N*/10 alkali per 1 g. of gelatin, which correspond to solutions at the extreme alkaline end of the neutralisation curve, at which  $OH'$  is appreciable,  $1 \times 10^{-4}$  or more, and will therefore have an effect on the transport member. Also all the solutions were so concentrated that activity coefficients were far removed from unity. It seemed of interest therefore to confirm or otherwise the mobilities in dilute solutions, using a different method.

### Composition of Solutions.

Solutions were made by adding various quantities of alkali free from carbonate to 1 per cent. gelatinate, and the diffusion potentials were

<sup>3</sup> *Biochem. Z.*, 1931, 233, 95.

<sup>4</sup> *J. Gen. Physiol.*, 1928, 11, 377.

measured against potassium chloride of the same potassium ion concentrations. In neutral solutions, from  $p_H = 6$  to  $p_H =$  about 8.5, the concentration of the potassium gelatinate was taken as equal to that of the alkali added,  $K' = G'$ , from  $2.8$  to  $4.4 \times 10^{-3} N$ . In such neutral solutions, hydrolysis of potassium gelatinate is low. In the more alkaline solutions, down to  $p_H = 10$ ,  $(OH')$  is still of a lower order of concentration, and  $G'$  is still nearly equal to  $K'$  ( $G' = K' - OH'$ ).

### Calculations of Mobilities.

In neutral solutions (I), of  $KG$ , concentration  $c_1$  and (II) of  $KCl$  concentration  $c_2$ , in which also  $c_1 = c_2$ , the diffusion potentials are given by :

$$E_{II-I} = \frac{RT}{F} \times (-1) \times \ln \frac{u_{K'} + v_{G'}}{u_{K'} + v_{Cl'}} \quad (1)$$

or 
$$E_{II-I} = \frac{RT}{F} \times (-1) \times \ln \frac{x_1}{x_2} \quad (2)$$

in which  $x_1$  and  $x_2$  are the conductivities.

The whole expression is positive, *i.e.* the  $KCl$  is positive to the  $KG$ , as was found to be the case. In alkaline solutions, the complete Henderson equation may be required (see page 579).

Examples of such calculations are given below. Mobilities (at 25°) selected<sup>5</sup> are

$$u_{K'} = 73.5, \quad v_{Cl'} = 76.3, \quad u_{H'} = 348, \quad v_{OH'} = 196.$$

By means of equation (1) :

$v_{G'}$	=	0	10	15	20	30	40	50
$E_d$	=	17.6	14.4	13.0	11.6	9.1	6.8	4.7

The potential, calculated for zero mobility of  $G'$ , is identical with the Donnan potential, set up by diffusion of  $x$  and  $K'$  and  $Cl'$  across a surface on one side of which is undiffusible  $G'$ . Diffusion will continue until the Donnan equilibrium is established when :

$$x(c_1 + x) = (c_2 - x)^2.$$

Since  $c_1 = c_2$  initially,  $x = \frac{1}{3}c_2$ , and

$$E = 58 \log \frac{c_1 + x}{c_2 - x} = 17.4 \text{ mv.}$$

The same potential should be found also in the more alkaline solutions, when  $G$  has zero mobility. For finite mobilities, values differ in neutral and alkaline solutions. Thus, if  $p_H = 10$ ,  $(OH') = 1 \times 10^{-4}$  in both solutions, the values of  $E_d$  corresponding to a given mobility  $v$ , will be greater, *i.e.* at  $v = 20$ ,  $E = 13.5$ ; at  $v = 30$ ,  $E = 11.0$ ; at  $v = 40$ ,  $E = 9.10$  mv.

### Valency of the Gelatin.

If the gelatin behaves as a multivalent electrolyte, the complete Henderson equation should be used, although the previous workers referred to have not considered this to be necessary. A few calculations on this basis will be added, in order to show how the calculated mobilities will be affected.

<sup>5</sup> MacInnes, Shedlovsky and Longworth, *J. Amer. Chem. Soc.*, 1932, 54, 2761; Jeffery and Vogel, *Nature*, 1932, 435, 775.

A summary of the equivalent weights of gelatin has already been given. The molecular weight, as estimated by osmotic and other methods, appears to be about 10,300. If it is assumed that this molecule remains undivided on combination, then the total concentrations of the various forms—uncharged, *Zwitterions* and ions—in 1 per cent. solutions is  $9.72 \times 10^{-4}$ . The negative valency of this molecule will increase from 0 to 8.25 as combination with alkali proceeds to saturation. When  $1 \times 10^{-4}$  equivalents of alkali have been added to 1.03 g. of gelatin, the latter has a negative valency of 1. Therefore valency  $z = (\text{c.c. of } N/10 \text{ alkali to 1 g. of gelatin}) \times 1.03$ .

In the case of the " $c$ " normal solutions of KG and KCl, the Henderson equation applied to multivalent electrolytes takes the form:

$$E_{H-1} = \frac{RT}{F} \frac{(\Sigma u_1 - \Sigma v_1) - (\Sigma u_2 - \Sigma v_2)}{(\Sigma u_1 z_1 + \Sigma v_1 z_1) - (\Sigma u_2 z_2 + \Sigma v_2 z_2)} \ln \frac{(u_1 z_1 + v_1 z_1)}{(u_2 z_2 + v_2 z_2)} \quad (4)$$

In the present case, the only valency differing from unity is that of the gelatin anion  $z_1$ .

In the calculations of the  $u$ ,  $v$  factors, mobilities may be all at  $25^\circ$  or all at  $18^\circ$  C., since ratios of mobilities are only slightly affected by temperature; but finally, of course,  $E$  in  $mv$ , is calculated at  $18^\circ$  or  $25^\circ$  by the appropriate constant 57.7 or 59.1 respectively. Since each valency, in solutions which have a constant concentration of 1 per cent. gelatin, corresponds to a single concentration of  $K'$  and  $G'$ , a number of graphs were constructed from equation (4) and integral values of " $z$ ."

POTENTIALS CALCULATED BY EQUATION (4).

$z$	2	$c = 1.04$	$p_H = 5.7$ .
$v$	10	20	30
$E_{H-1}$	13.7	10.6	8.05
$z$	3	$c = 2.01$	$p_H = 7.5$ .
$v$	10	20	30
$E$	13.1	9.85	7.3
$z$	4	$c = 3.88$	$p_H = 9.3$ .
$v$	10	20	30
$E$	12.6	7.15	6.1

Thus the potentials are lower than those calculated by equation (1) for the same mobilities; they fall, although only slightly, as the valency increases on addition of more alkali, and also with increase in  $v'$ , the mobility of gelatinate ion. Intermediate valencies lie on interpolated lines, from which  $v'$  corresponding to any experimental  $E$  may be found.

**Example.**—At a concentration of  $2.6 \times 10^{-3}$ :

$$z = \frac{2.6 - 1.04}{2.91 - 1.04} \div 2 = 2.68.$$

If  $E_d = 10$  mv.,  $v$  is 20.5 as compared with 27 by equation (1).

Also if  $z = 4$ , and  $E_d = 12.6$ ,  $v = 10$  by the valency formula as compared with 12 by equation (1). Thus mobilities given by the valency formula of the multivalent ions will be about 20 per cent. lower than those per equivalent of gelatin.

In alkaline solutions, the valency equations indicate only slight changes of  $E$  with  $v$ , thus at  $p_H = 10$ :  $v = 0$ ,  $E = 17.1$ ;  $v = 40$ ,  $E = 15.0$  mv. Since in the alkaline solutions, values of  $E$  above 11.0 were not found, it appears that the results of the simple formula are more in accordance with facts presented here.

## Experimental.

The purification of gelatin, starting from "coignet gold label" or "best leaf bronze," followed in general the lines indicated in the last paper. For reasons already given, normal *ku* calomel half-cells were used, both in measurements of diffusion potentials, and in those of hydrogen potentials. A Cambridge potentiometer was employed throughout. The indicator of null potential was a Cambridge A.M. galvanometer, short period type, having a sensitivity of 0.35 microvolt per 1 mm. scale deflection at 1 metre.

A stock solution of purified gelatin (5 per cent. or more of gelatin) had previously been analysed by evaporation in platinum, the ash also having been determined. A portion of the melted stock was weighed, and made up with conductivity water to about 50 g. short of the final weight required. Decinormal potassium hydroxide free from carbonate was then added in an amount calculated to give  $p_H$  within the neutrality range, which was estimated by a Lovibond comparator (B.D.H. pattern) and standard coloured glasses. If  $p_H$  was too low, more measured alkali was added. The

FIG. 1.

solution was then made up to the correct weight with pure water, and the  $p_H$  redetermined colorimetrically. A current of hydrogen was started through a sample in a hydrogen electrode vessel of the Sand-Hildebrand type, the potentials being measured at intervals until they became constant, which might require several hours. In the meantime, solution II. of KCl having exactly the same concentration as the KG is made, and if the gelatin solution were definitely alkaline, the required slight excess of alkali was added to the KCl. This solution is not buffered, but retains its alkalinity long enough for a measurement of  $OH'$  by the hydrogen electrode. Conductivities (at 28°) of the KCl and KG were then determined in a U tube of high resistance capacity, using the method of Christensen as described by Gram & Cullen.<sup>6</sup> These conductivities served several purposes *i.e.* :

- (1) A control of the concentration of the KCl.
- (2) A control of the KG, from which also the mobilities of the gelatin ion can be calculated.<sup>7</sup> These mobilities are subject to rather high errors, being the differences of two larger magnitudes.

<sup>6</sup> J. Biol. Chem., 1923, **57**, 477.

<sup>7</sup> Cf. König and Pauli, *Biochem. Z.*, 1932, **252**, 325.

(3) Diffusion potentials could be calculated independently by equation (2) above. The two sets of values, denoted on Fig. 1, by X were sometimes, but not always, in agreement.

Salt bridges were also made containing the KG in jelly form, and the KCl in agar jelly. These were used to avoid all possibility of diffusion of KCl from the normal calomel KCl electrodes to the junction. Finally, the diffusion potentials were measured, with necessary checks. Each experiment with preparations and checks occupied one to two days. A number of such experiments have given additional information as to the relative value of the different junctions.

### Static and Flowing Junctions.

In the course of this work, it appeared that the flowing junctions were not so well suited for solutions containing protein ions.

The apparatus with large tap of Ferguson v. Lente and Hitchens,<sup>8</sup> which had been proved to give excellent results with electrolytes, gave less constant and often very low potentials with gelatin solutions. The relatively large flowing junctions of the MacInnes, Yeh,<sup>9</sup> and Scatchard type<sup>10</sup> gave rather better results. A large static junction was preferable to either flowing type. In the later experiments these junctions were always used, and were made in a boiling tube having an internal diameter of about an inch. Such junctions are not much affected by complete or partial gelatinisation. Potentials between KG (gel) and KCl were usually, but not always, 1 to 2 millivolts higher than those between KG (sol) and KCl.

**Example.**—An alkaline solution of KG was made having  $[K'] = 0.00606$   $[OH'] = 0.0001$ ,  $[G'] = 0.00596$ . The corresponding KCl having

$$[K'] = 0.00608 = [Cl']$$

was buffered with  $Mg(OH)_2$ , so that  $OH' = 0.0004 = \frac{1}{2}Mg''$ . Taking into account the  $\nu_{Mg} \cdot c_{Mg}$  factor which was only about 1/20 of  $\nu_{K} \cdot c_K$  the full Henderson equation gave:

$$\begin{array}{cccc} E' & 0 & 20 & 30 & 40 \\ E & 17.2 & 13.6 & 11.1 & 8.8 \text{ mv.} \end{array}$$

The observed potential of 0.0 mv. agrees with a mobility of nearly 40.

These results are in fair agreement with those of Ferguson and Schluchter,<sup>8</sup> obtained in solutions of much higher gelatin concentration.

### Comparison with Mobilities Determined by Other Methods.

The mobilities of various proteins have been investigated by a modified Hittorf method in which the changes of concentration after passage of a measured quantity of electricity are determined by micro-Kjeldahl analysis.<sup>11</sup> That of ovalbumin rose from 2.1 to 2.8  $\mu$ /sec. as the c.c. of N/10 alkali per g. were increased from 5 to 15—a steep rise to a well-defined maximum. Corresponding values for serum albumin were 1.1 at 5 c.c. to a maximum of 2.9 at 15 c.c. Pseudo-globulin gave a flat graph with a maximum of 1.88 at 5 c.c. and  $p_H = 10.53$ , and then nearly constant velocities with further additions of alkali.

The method of cataphoresis has also been employed. The velocity of ovalbumin rose steadily to 1.0 at  $p_H = 6.0$ , while that of gelatin increased only slowly,<sup>12</sup> to about 0.8 at  $p_H = 6.0$ .

<sup>8</sup> *J. Amer. Chem. Soc.*, 1932, **54**, 1279.

<sup>9</sup> *Ibid.*, 1921, **43**, 2563.

<sup>10</sup> *Ibid.*, 1925, **47**, 698. <sup>11</sup> König and Pauli, *Biochem. Z.*, 1932, **252**, 325.

<sup>12</sup> Abramson, *J. Gen. Physiol.*, 1932, **15**, 575.

Prideaux and Howitt<sup>13</sup> also found a steady increase in the velocity of ovalbumin, to 1.92  $\mu$ /sec. at  $p_H = 9.38$ , and a gradual increase in that of gelatin to 0.8 at  $p_H = 9.3$ . These values must, of course, be multiplied by 9.65 to convert them with electrolytic mobilities. The present values show a rather more rapid increase in the mobility of gelatin, than that found by kataphoresis. If, however, the mobilities of  $\text{OH}'$  are not introduced into the calculations, the mobilities  $v'$ , like the diffusion potentials, remain constant with increasing combination.

### Diffusion and Zeta Potentials.

On account of the unfavourable nature of the calculation from potentials to mobilities, it is better to compare the diffusion potentials with zeta, or phase limit potentials of the double layer between the gelatin solution I. and the electrolyte solution II., which takes part in the kataphoretic movement. By the equation of v. Helmholtz and v. Smoluchowski

$$\zeta = \frac{4\pi\eta V}{XK}$$

in which "V" is the velocity,  $\eta$  the viscosity of solutions,  $K$  their dielectric constant and  $X$  the potential gradient in volts/cm. Putting in the values in c.g.s. units and taking  $\eta = 0.01$ ,  $K = 82$ , the factor works out at 12.6. Abramson<sup>14</sup> used 12.9. In the present case, a rounded factor of 13 has been used, which gives potentials plotted in Fig. as  $\Delta$ . Thus, from the velocities of Prideaux and Howitt.<sup>13</sup>

At $p_H = 5.45$	5.93	6.6	7.15	8.0	9.3
$\zeta = 7.8$	11.9	10.6	9.6	11.7	11.7 mv.

Evidently the zeta potentials are of the same order, and vary in the same way as the diffusion potentials. But the mobilities which give rise to identical potentials are quite different according to whether they are related by the phase boundary equations ( $\zeta$  and  $v$ ) or by the ionic equations ( $\bar{E}$  and  $v'$ ).

## REVIEWS OF BOOKS.

**Atomic Physics.** By MAX BORN. Pp. xii and 352. Blackie & Sons, Ltd., London. Price, 17s. 6d.

Professor Born's survey of atomic physics is admirably adapted to the needs of junior honours students, and, indeed, students of higher grade will find it helpful in providing a survey, in very moderate compass, of important modern work and ideas.

The kinetic theory of gases, the nuclear atom, wave-corpuscles, atomic structure and spectral lines, electron-spin and Pauli's principle, quantum statistics and molecular structure—these are the principal topics to which the book is devoted.

Mathematical proofs are collected in some thirty appendices, which occupy nearly one hundred pages in a total of three hundred and fifty. Thus, although, as is to be expected, theoretical discussions bulk largely in the book, the arguments developed in the text are not over-laden with mathematical formulae.

The book may be unreservedly commended.

A. F.

<sup>13</sup> *Proc. Roy. Soc.*, 1929, 126A, 126.

<sup>14</sup> *J. Amer. Chem. Soc.*, 1928, 50, 390.

**The Restless Universe.** By MAX BORN. Pp. 278. Blackie & Sons, Ltd., London. Price, 8s. 6d.

Professor Born's name has to be added to the long list of those who have endeavoured, with varying degrees of success, to *unscramble the inscrutable*. As was to be expected, his attempt to draw a world-picture which the layman may understand, is highly original. In a text of less than three hundred pages, he starts with a discussion of kinetic theory couched in terms so simple as to demand a picture of a rapidly-emptying classroom to illustrate the meaning of rarefaction. Yet, unhesitating and unrelenting, he carries us along through a description of electrons and ions, waves and particles, atomic structure and nuclear physics to a triumphant conclusion which demands some account of the latest particles and of Pauli's exclusion principle.

Not the least interesting feature of the book is the series of seven moving pictures printed on the specially broad margins of the pages, so that, by rapidly flicking over the pages with the thumb, one is enabled to visualise something of the motion of the electron in the hydrogen atom, or of the flux of the field near a Hertzian oscillator.

"A world without models, indeed! *Plus ça change*. . . .

A. F.

**Worlds without End.** By H. SPENCER-JONES. Pp. xv and 262. English Universities Press, London. Price, 5s. net.

The Astronomer-Royal's introduction to cosmology is *different*. His story, told in plain and telling phrases, opens with an account of the principal astronomical facts and theories concerning the Earth on which we live. Then he gives a similar discussion of the life-history of our nearest neighbour, the Moon, and, proceeding in his argument outward through the cosmos, he tells us of comets and shooting stars, the Sun, our own stellar world, and the extra-galactic universes. There is little space devoted to speculation on origins and endings— an impressive tale is told in unadorned and sober fashion and the reader is left in no doubt about what, in modern astronomy, is well-established theory, and what is not-so-well-established speculation.

The book is an ordered storehouse of essential and fundamental facts, and provides an admirably proportioned picture of our universe as we view it to-day. It is excellently produced and illustrated, and should find a wide circle of appreciative readers.

A. F.

**Handbuch der experimental Physik.** Bd. xi-2. By W. MEISSNER. Pp. xii and 544. Akad. Verlags M.B.H., Leipzig, 1935. Price, RM. 42. Bound, RM. 44.

This volume is divided into three main sections. The first part deals with **resistance** measurements for pure metals, alloys and compounds, with the **relation** between thermal and electrical conductivity, with the effect produced on resistance by magnetic fields and by deformations; with **supra-conductivity**, and with electron theories, new and old, of electrical conductivity.

The second section is concerned with galvano- and thermo-magnetic effects (Hall, Ettingshausen, Righi-Leduc and Ettingshausen-Nernst effects and their relations), and the third section deals with thermo-electricity.

The volume is encyclopædic in its range, and very few contributions to the subjects of any value have escaped the notice of the authors. Brief but adequate discussions of theoretical matters of primary importance are provided, but the bias of the treatment is, naturally, towards the experimental side.

It is as much a work of reference as a student's handbook—the bibliography is specially full and complete, the number of references exceeding twelve hundred—and is quite indispensable to any serious worker in these fields. The volume is admirably produced, and is an important addition to a series of international repute.

**Léemann. Le Pansoma et la Géometrie de l'Énergie.** (Georg & Co., Geneva, 1935. Price 15 Swiss francs.)

"Un pansome est une entité énergétique tridimensionnelle, indestructible et indivisible, à délimitation nette par des surfaces pansomiques, à contenu énergétique absolu et constant, la seule variabilité fondamentale qu'il est capable de manifester étant cette dernière."

In the light of this definition, "sur laquelle nous basons toute notre théorie," the author discourses vaguely and benevolently on the pansomic structure of the atom, on ether and relativity, on radiation, cosmology, the colloid state, causality, karyokinesis, muscular contractions, psychology. . . .

A distinguished Anglican prelate spent some years of his life as the vicar of a parish in the North of England. When, on the occasion of his promotion, he paid a round of farewell visits to his parishioners, he was greeted by a farmer's wife with "I hear as yo're goin', Vicar. Well, if tha hasn't done much good, tha's not done any harm."

Which saying is a parable.

A. F.

**Electron Diffraction.** By R. BEECHING. (London: Methuen & Co. Pp. viii and 106. Price 3s.)

In this little book the Author has fully maintained the high standard already set up by this series of monographs. The discussion of Kikuchi lines in the earlier part of the book is rather inconclusive, but this is due to present ignorance as to the true nature of these effects. The writer treads very warily when such regions of the subject come under consideration but this is undoubtedly the best thing to do in a small monograph. The sections on crystal structure, atomic scattering factor, and structure factor, could have been more closely woven together, although all the necessary information is certainly present in the book taken as a whole. It is also felt that some further mention could have been made as to experiments on polish effects on metals. Apart from these mild criticisms the work is very complete and is an excellent, up-to-date account of the subject.

J. A. D.

# PROPERTIES OF ELECTROLYTIC SOLUTIONS. XVIII. MOLECULAR POLARISATIONS AND POLAR MOMENTS OF SOME ELECTROLYTES IN BENZENE SOLUTIONS.

By JOHN A. GEDDES<sup>1</sup> AND CHARLES A. KRAUS.

*Received 23rd December, 1935.*

A study of the conductance of solutions of electrolytes in non-polar media<sup>2</sup> has shown that while such solutions exhibit properties similar to those of solutions of electrolytes in polar media, only a very small fraction of the electrolyte is actually concerned in the conduction process at a given instant—about one part per million. It may be inferred that the bulk of the electrolyte is present in the form of neutral molecules or aggregates which do not contribute to the conduction process. The results at higher concentrations indicate the formation of highly complex aggregates, both charged and uncharged, the degree of complexity increasing with increasing concentration. Molecular weight determinations with solutions of electrolytes in benzene go to show that in the neighbourhood of  $10^{-3}$  *N*, the molecular weight of many electrolytes approximates their formula weight,<sup>3</sup> although, depending upon the character of the electrolyte, the degree of complexity may be greater. We thus have conclusive evidence that, in general, electrolytes dissolved in non-polar solvents exist, for the most part, in the form of neutral aggregates comprising two ions at lower concentrations and becoming more complex as the concentration increases. A study of the conductance or of the mean molecular weight of electrolytes fails to give an insight into the structure or nature of these complexes. If, however, the ions exist as such in their two-ion complexes, a study of the dielectric behaviour of solutions of electrolytes in a non-polar medium should give direct information with respect to the existence of such complexes and the change of the molecular polarisation of such solutions with increasing concentration should supply information with respect to the existence of more complex structures.

The earlier investigation of Hooper and Kraus,<sup>4</sup> on the dielectric behaviour of solutions of electrolytes in benzene, demonstrates, beyond question, that in these solutions electrolytes possess a high polar moment. Thus, we have direct evidence of the existence of ionic dipoles in such solutions.

<sup>1</sup> This paper is based on a thesis presented by John A. Geddes in partial fulfilment of the requirements for the degree of Doctor of Philosophy in the Graduate School of Brown University, June, 1935.

<sup>2</sup> Fuoss and Kraus, *J. Am. Chem. Soc.*, 1933, **55**, 21, 1019, 3614; Kraus, *Trans. Electroch. Soc.*, 1934, **66**, 179.

<sup>3</sup> Batson and Kraus, *J. Am. Chem. Soc.*, 1934, **56**, 2017; D. A. Rothrock, Jr., unpublished observations in the Brown Laboratories.

<sup>4</sup> Hooper and Kraus, *J. Am. Chem. Soc.*, 1934, **56**, 2265.

Unfortunately, in order to be able to interpret the results of dielectric constant measurements of electrolytes in benzene solution with any degree of assurance, it is necessary to carry the measurements to concentrations at least as low as  $10^{-4}$  *N* and the precision in the case of the Hooper and Kraus measurements was not sufficiently high to fix the limiting form of the polarisation curves with certainty. The present investigation has been directed to improving the precision of the measurements and supplying data with respect to the polarisation curves of electrolytes at low concentrations.

### Experimental.

**Method.**—The method employed in the present investigation was that of Hooper and Kraus with some slight modifications. Their method, in turn, was a modification of the resonance method of Wyman.<sup>6</sup> The method consists essentially in introducing into the medium a resonator of fixed inductance and capacity. A variable oscillator adjacent to the resonator is adjusted to resonance with the fixed resonator, resonance being indicated by a maximum of the current in the plate circuit of the variable oscillator. To determine the frequency of the oscillator at resonance, it is tuned to known harmonics of a crystal oscillator with which it is inductively coupled, zero heat being indicated in a telephone. In general, the frequency of the resonator will lie between two adjacent harmonics of the crystal oscillator and in order to determine the frequency of the resonator, a small cylindrical condenser, one cylinder of which is mounted on the carriage of a micrometer screw, is introduced into the circuit of the variable oscillator. The frequency of the variable oscillator is a linear function of the setting of the variable condenser. In practice, the condenser is set to a harmonic on one side of the resonance frequency, then to the resonance point, and finally, to the harmonic on the other side of the resonance point. By a linear interpolation between the two harmonics, the frequency of the resonator is obtained in terms of known harmonics of the crystal. If  $h_0$  is the harmonic number of the resonator in air, and  $h$  is the harmonic number of the resonator in the medium, then the dielectric constant of the medium is given by the expression:  $D = (h_0/h)^2$ . The actual frequency of the crystal does not enter. The details of the apparatus have been described by Hooper and Kraus, and need not be given here. It should be mentioned, however, that for the purpose of making connection between the movable cylinder of the precision condenser and the oscillating system, a fixed wire and mercury trough were employed in place of a flexible wire connection. It was found that a flexible connection produces sufficient change in the inductance of the circuit to lead to appreciable variations in the readings.

The resonator consisted of a pair of coaxial brass cylinders connected by a single loop of  $\frac{1}{4}$ -inch brass rod. The resonator was silver-plated before use. Its frequency in air was 119 megacycles, which corresponds to a wave-length of 2.52 metres. In order to establish the absence of anomalous dispersion, one series of measurements was carried out with tributylammonium picrate, using a resonator having a frequency of 50 megacycles. The results are given in Table III.(b), and agree with those obtained at the higher frequency within the limits of experimental error.

In carrying out the measurements, the resonator was suspended in pure benzene contained in a cylindrical glass tube having a diameter approximately twice that of the resonator. After determining the resonance point in benzene, a known weight of a dilute solution of the electrolyte was introduced into the benzene by means of a weight burette. After adding the solute, the solution was vigorously stirred, the resonator being lifted above the surface of the solution during the process. After returning

<sup>6</sup> Wyman, *Physic. Rev.*, 1930, **33**, 623.

and lifting the resonator out of the solution several times, the latter was again stirred, and this process was repeated until constant readings were obtained for the frequency of the resonator. It is very important that the solution be homogeneous.

The tube containing the solution and resonator was placed in a double-walled tube, through which liquid was circulated by means of a pump from a thermostat whose temperature was maintained constant at 25.00°. The oil jacket was, in turn, placed in a large Dewar tube. Temperatures were in all cases maintained constant within limits set by the precision of the measurements. The variable oscillator was mounted on a pair of rails, and its position with respect to the resonator could be adjusted readily by means of a rack and pinion. The current in the plate circuit of the variable oscillator was read on a milliammeter. The relative position of oscillator and resonator was so adjusted as to give a suitable value of the current. If the current is too low, the maximum cannot be satisfactorily determined, while if the current is too large, the resonance curve of the current is unsymmetrical.

The apparatus permitted of measuring the dielectric constant of solutions reproducibly within a few units in the fifth place of decimals. The absolute variation is somewhat higher at higher than at lower concentrations, probably owing to the fact that with increasing concentration the conductance of the solutions increases, as a result of which the resonance curve becomes appreciably flatter and it is, accordingly, more difficult to locate the maximum.

**Materials.**—Thiophene-free benzene was washed with concentrated sulphuric acid, water, dilute sodium hydroxide solution and again water. After drying over calcium chloride, it was fractionally crystallised and then refluxed over sodium-lead alloy (10 per cent. Na) in a still from which it was distilled as needed. M.P. 5.48°.

All salts were prepared in the laboratory and purified by recrystallisation from suitable solvents to constant melting-points. The melting-points were as follows: tetraisoamylammonium picrate, 85°; tetraisoamylammonium thiocyanate, 88°; tri-isoamylammonium picrate, 127°; tetra-*n*-butylammonium picrate, 89.5°; tri-*n*-butylammonium picrate, 106°; tetra-*n*-butylammonium perchlorate, 207°; tri-*n*-butylammonium iodide, 102°; tri-*n*-butylammonium bromide, 75°; tri-*n*-butylammonium chloride decomposes without melting at 182°; tetra-*n*-butylammonium acetate, 116°; tetra-*n*-butylammonium bromide, 115.5°; tetra-*n*-butylammonium hydroxytriphenylboron, 145.5°.

**Constants.**—The density effects due to these organic electrolytes in benzene are small and, rather than to attempt direct measurement of the densities of the extremely dilute solutions, it seemed preferable to measure the densities at higher concentrations and to compute the density values at lower concentrations according to a linear function. The density values as experimentally determined are given in Table I.

Indices of refraction are not available for determining the correction due to distortion polarisation in the case of the electrolytes employed. Accordingly, values were computed from atomic constants as given in Landoldt and Börnstein's Tables. The error involved, due to uncertainties in these values, is negligible, since the total polarisation is very large in comparison with the correction, which seldom exceeds 1 per cent. The values employed are given in Table II.

TABLE II.—OPTICAL CONSTANTS.

### Results.

The experimental results are given in Table III. in which the mol fraction is given in the first column, the observed dielectric constant in the second column, and the molecular polarisation of the electrolyte, calculated as usual according to the Debye formula, in the last column. In making the computations, the dielectric constant of pure benzene is taken to be 2.26800, which corresponds to a polarisation of 26.5392 c.c. All measurements were carried out at 25.00°.

### Discussion.

Values of the molecular polarisation for the different salts measured above are shown graphically in Figs. 1, 2, and 3, the polarisation being plotted as ordinate against mol fraction as abscissa. The limiting polarisations for these electrolytes were obtained by extrapolating the curves to zero concentration and values so obtained are given in the second column of Table IV. Polar moments as computed from the polarisation values, corrected for distortion polarisation, are given in column 3, and the distance between centres of charge  $\alpha = \mu/4.77 \times 10^{-10}$  are given in the last column.

The first conclusion to be drawn from these results is that, in a non-polar medium, and at relatively low concentrations, electrolytes exist largely as ionic dipoles. The value obtained for the distance between charges is of an order of magnitude such as to indicate that the charges are widely separated, and that the degree of separation depends upon

the size and configuration of the ions. The largest polar moment is obtained for tetra-*n*-butylammonium hydroxytriphenylboron, which is composed of two very large ions. In the negative of this electrolyte, the hydroxyl ion is co-ordinated with the boron atom of triphenylboron. The quaternary ammonium picrates show high polar moments, indicating that, while the charge on the negative ion is doubtless largely localised on the phenolic oxygen atom, it is prevented from approaching closely to the positive charge on the nitrogen atom by the alkyl group surrounding that atom as well as by the nitro-groups adjacent to the phenolic oxygen of the picrate ion. If one of the alkyl groups of the ammonium ions is replaced by hydrogen, as in the case of tri-*iso*amylammonium picrate, for example, the moment is greatly reduced, doubtless because of the closer approach of the phenolic oxygen to nitrogen. Thus, the moment of tetra-*iso*amylammonium picrate is 18.3 Debye units, while that of tri-*iso*amylammonium picrate is only 13.3 D. The distance between charges for the same electrolytes is 3.82 Å and 2.79 Å, respectively, a difference of approximately 1 Å. With the same quaternary ammonium ion, but replacing the picrate ion by the bromide ion, the polar moment is greatly reduced, doubtless due to the smaller size of the bromide ion. Thus, for tetra-*n*-butylammonium picrate, the polar moment is 17.8 D, and for the corresponding bromide, 11.6 D. For tetra-*n*-butylammonium acetate, the polar moment is 11.2 D, only slightly lower than that of the bromide, indicating that the charge is largely localised on the carboxyl group of the acetate ion. Replacing one of the butyl groups of the quaternary bromide by hydrogen leads to a large reduction in the polar moment—from 11.6 D for tetrabutylammonium bromide to 7.61 D for tri-*n*-butylammonium bromide. The polar moments of tri-*n*-butylammonium halides diminish in the order: iodide, bromide, chloride, as is shown by the values: 8.09 D, 7.61 D, 7.17 D; the corresponding distances between charges are: 1.69 Å, 1.590 Å, 1.50 Å. It is clear that as the ions are smaller, the polar moments are likewise smaller. The deformation of the ions must, however, be considerable since, in passing from iodide to bromide to chloride, the change in the distance between charges at each step amounts to only about 0.1 Å. That the deformation should be large is not surprising when we consider the value of the forces concerned. In the case of tri-*n*-butylammonium chloride, the force acting between a pair of charges is of the order of  $10^{-8}$  dyne. If this force were interpreted in terms of pressures, it would be of the order of  $10^6$  atmospheres. In the case of electrolytes with more complex ions, we probably have not only deformation of electron shells, but also distortion of valence bonds.

According to the form of their polarisation-concentration curves, the electrolytes fall into three groups. In the first group, illustrated in Fig. 1, the polarisation falls off linearly with concentration; in the second group, illustrated in Fig. 2, the polarisation curve falls off rapidly and non-linearly at higher concentration; and in the third group, illustrated in Fig. 3, the polarisation is practically independent of concentration.

To return to the group of electrolytes illustrated in Fig. 1, it will be noted that the curves are, in general, the steeper the greater the value of the polar moment. Fuoss<sup>6</sup> has derived an equation for the slope  $dP/df$  of the polarisation curve for the case of ellipsoidal dipoles. Aside from the constants of the solvent medium, such as dielectric constant,

<sup>6</sup> Fuoss, *J. Am. Chem. Soc.*, 1934, 56, 1031.

density, and molecular weight, the slope of the curve depends on the moment of the dipole and the two diameters of the ellipsoid. The relation obtained is applicable only so long as  $\lambda$ , the ratio of major to minor diameters, is less than  $2^{-1/2}$ .

Provided that it is legitimate to consider that, in the case of electrolytes whose plots appear in Fig. 1, the electrical and spatial configurations

FIG. 1.—Polarisation curves of ionic dipoles which show little tendency to associate.

for the axial ratio,  $\lambda$ , varying between 0.1 and 0.65, the minor diameter varies only between 4.76 Å and 5.17 Å. If we assume an axial ratio of 0.5 (which seems reasonable in view of this computation), we may expect that the values obtained for the minor diameters will be approximately correct. In Table V. are given values of the polar moments, of the slopes  $dP/df$  of the polarisation curves and of the diameter of the minor axis  $\lambda a$  for the series of electrolytes whose curves appear in Fig. 1.

TABLE V.—COMPUTED MINOR DIAMETERS OF ELLIPSOIDAL MODEL.

Electrolyte.	$\mu \times 10^{18}$ .	$dP/df \times 10^{-6}$ .	$\lambda a \times 10^8$ .
Tetra- <i>n</i> -butylammonium hydroxy-triphenylboron . . . .	19.7	-160	6.37
Tetra- <i>iso</i> amylammonium picrate . . . .	18.3	-32	6.28
Tetra- <i>n</i> -butylammonium picrate . . . .	17.8	-17	6.28
Tri- <i>iso</i> amylammonium picrate . . . .	13.3	-12.5	5.05
Tri- <i>n</i> -butylammonium picrate . . . .	13.1	-8	5.02
Tetra- <i>n</i> -butylammonium acetate . . . .	11.2	-3	4.59

The values obtained for  $\lambda a$ , the minor diameter, are reasonable as to order of magnitude. The more complex electrolytes have the larger diameters, and the diameter is relatively independent of the polar moments themselves.

Values of  $\lambda a$  may be computed in similar manner from cryoscopic data.<sup>7</sup> For tri-*iso*amylammonium picrate, the value computed from

freezing-point data is 5.66 Å. in contrast to 5.05 Å as found in the present investigation.

In the case of electrolytes with two relatively symmetrical ions, such as those of the electrolyte appearing in Fig. 2, the polarisation curve falls off very rapidly with concentration. It may be in-

FIG. 2.—Polarisation curves of ionic dipoles which show marked association.

ferred that this is due to the association of dipoles to quadrupoles and more complex structures. Hooper and Kraus<sup>4</sup> have observed the same type of curve in the case of tetra-*iso*amylammonium bromide and silver

Cryoscopic measurements with salts of this type in dioxane and benzene indicate a high degree of association of these electrolytes at higher concentrations. The molecular weights of tetra-*iso*amylammonium nitrate in dioxane and of the thiocyanate of the

FIG. 3.—Polarisation curves of ionic dipoles which exhibit a complex type of association.

same ion in benzene are several times the formula weight even at concentrations as low as  $10^{-3}$  N. The same is true of tetra-*n*-butylammonium

<sup>7</sup> Fuoss and Kraus, *J. Am. Chem. Soc.*, 1935, 57, 1.

perchlorate in benzene. At concentrations in the neighbourhood of  $10^{-3}$  *N*, the molecular weight of salts of the type here discussed rises as high as from five to ten times the formula weight, indicating the rapidly increasing complexity of the solute molecules with increasing concentration.

The curves for tri-*n*-butylammonium-iodide, bromide and chloride, as shown in Fig. 3, are practically horizontal, straight lines. One might conclude, on the basis of polarisation data alone, that these dipoles undergo no association. Cryoscopic measurements, however, show clearly that these salts are associated at higher concentrations, although not to as great an extent as the salts illustrated in Fig. 2. Thus, cryoscopic measurements with tri-*n*-butylammonium iodide<sup>8</sup> indicate an association of 10 per cent. at  $10^{-3}$  *N*, although the polarisation curve indicates no deviations greater than 1 per cent. up to that concentration. At higher concentrations, cryoscopic measurements indicate rapid increase in the complexity of tri-*n*-butylammonium iodide.

Fuoss<sup>6</sup> has shown that when  $\lambda = 2^{-1/3}$  in the ellipsoidal model, the theoretical slope of the polarisation curve is zero. Debye<sup>9</sup> has shown that for spherical molecules containing a point dipole at the centre, the polarisation increases with concentration, owing to the fact that the dipoles associate end to end. In the case of electrolytes, such as the tri-butylammonium halides, a proper form of the model is probably an approximate sphere with a dipole displaced far to one side of the centre. This case has not been treated theoretically. On the basis of dielectric constant and cryoscopic measurements, we must conclude that association in the case of the tertiary ammonium halides is complex, some of the dipoles associating to form molecules with increased moments, and others associating to form molecules with decreased moments. It is not possible to analyse this case further on the basis of present data.

### Summary.

The dielectric constant of solutions of a number of salts in benzene has been measured at low concentrations and polarisation values, as well as polar moments have been computed therefrom.

High values obtained for polar moments, ranging from 7 D. to 20 D., indicate the existence of electrical dipoles in these solutions. According to the form of their polarisation curves, the electrolytes fall into three groups, namely: (1) in which polarisation diminishes linearly with concentration; (2) in which a large and non-linear decrease occurs; and (3) in which the polarisation is independent of concentration. The form of the polarisation curves is related to the structure of the ions of the dipoles concerned, and is determined by association of dipoles to more complex structures. The results of the present measurements are in accord with freezing-point and conductance measurements in the same solvent.

# PROPERTIES OF ELECTROLYTIC SOLUTIONS, XIX. CONDUCTANCE OF MIXED ELECTRO- LYTES IN ETHYLENE CHLORIDE. TETRA- BUTYL- AND TETRAMETHYL-AMMONIUM PICRATES.

By DARWIN J. MEAD<sup>1</sup> WITH RAYMOND M. FUOSS AND CHARLES A. KRAUS.

*Received 23rd December, 1935.*

## I. Introduction.

In solvents of high dielectric constant where association of 1-1 electrolytes is usually negligible, conductances of mixed electrolytes are not additive; it has been shown that the relaxation effect depends on the mobilities and mol-ratios of all species of ions present.<sup>2</sup> Furthermore, if association occurs, as is the case in most non-aqueous solvents,<sup>3</sup> the departure from additivity is still greater if the dissociation constants of the components of the mixture differ appreciably; the dissociation of a weak electrolyte is, to use the phraseology of the Arrhenius theory, repressed by the presence of a strong electrolyte with a common ion.<sup>4</sup> Both of these effects decrease, of course, with decreasing concentration. It is the purpose of this paper to present data on the conductance of tetramethyl- and tetrabutyl-ammonium picrates, singly and in various mixtures, in ethylene chloride ( $D = 10.23$ ), and to compare the experimental results with theoretical equations which are developed in this paper. This comparison will permit a rigorous cross-check of both theory and experiment. Improvements in experimental technique, which have greatly increased the relative precision and improved somewhat the absolute accuracy of conductance determinations in ethylene chloride, are also described: relative values are now self-consistent within a few hundredths of a per cent., and absolute values are reproducible to about 0.1 per cent.

<sup>1</sup> This paper comprises part of a thesis submitted by Darwin J. Mead in partial fulfilment of the requirements for the degree of Doctor of Philosophy in the Graduate School of Brown University.

<sup>2</sup> Onsager and Fuoss, *J. Physic. Chem.*, 1932, **36**, 2689.

<sup>3</sup> Fuoss, *Chem. Rev.*, 1935, **17**, 27.

<sup>4</sup> The modern theory of association and the older dissociation theory of Arrhenius lead to results that are formally similar in their application, although they differ widely in the underlying mechanisms postulated. The former assumes *a priori* that only ions are present and that these may associate under the action of Coulomb forces provided that the energy relationships permit, the original ions retaining their identity in the associated complex. The dissociation theory of Arrhenius treats the equilibrium of electrolytes from the thermodynamic point of view, assuming that ions are formed from neutral molecules by a process of dissociation. Strictly speaking, no assumptions are here made as to the nature of the neutral molecule, nor of the mechanism involved in the process of dissociation or association. Actually, the older theory assumed the neutral molecules to be combinations of atoms which dissociated with separation of charge to form ions. To be consistent, we should speak of association rather than dissociation constants; we shall, however, retain the conventional nomenclature, since this has been generally employed throughout the literature.

## II. Experimental.

**Apparatus.**—The electrical equipment is essentially the same as that used by Cox, Kraus and Fuoss.<sup>6</sup> We have supplemented the known resistances available by a 0.1-1.0 megohm non-inductive, non-capacitative resistance<sup>6</sup> box and take this opportunity to thank Professor M. Wien for his kindness in having the box made for us.

The conductance cells were of the Erlenmeyer type described by Kraus and Fuoss.<sup>7</sup> The electrodes were unplatinised. Cell constants were determined by comparison with a cell whose constant was 0.38743, according to Jones and Bradshaw's data<sup>8</sup> for 0.1 demal potassium chloride solution at 25°. The two cells used had constants of 0.10683 and 0.21299, respectively (each an average of five separate determinations which agreed within 0.02 per cent.); polarisation<sup>9</sup> and lead effects<sup>10</sup> were negligible, since the ratio of cell constants showed a variation of less than 0.05 per cent. with resistance (8000-400,000 ohms) and frequency (400-2000 cycles).

**Materials.**—Ethylene chloride was purified by the method of Cox, Kraus and Fuoss, with one change: after standing for about a week over activated aluminum oxide in the last step of the purification, the ethylene chloride was separated from suspended oxide by filtering through glass cotton (a very fine glass wool, 2-3 microns average diameter, manufactured by the Owens-Illinois Glass Co., Toledo, Ohio) in an all-glass apparatus designed to exclude atmospheric moisture. This procedure gave consistently lower values of solvent conductance than when the solvent was distilled from the aluminum oxide. The solvent conductance varied from  $0.6 \times 10^{-11}$  to  $5.0 \times 10^{-11}$  mho; since the specific conductance for the most dilute solution was about  $5 \times 10^{-7}$ , the solvent correction was entirely negligible. In view of the uncertainty usually involved in solvent corrections, we are convinced that reliable results in non-aqueous solutions can only be obtained if the correction is made unnecessary by reducing it to a value within other experimental errors.

Tetrabutylammonium picrate (m.p. 89.5°) was prepared by the method of Cox, Kraus and Fuoss, except that the final recrystallisation was made from alcohol (2 c.c. per gram, 85 per cent. yield on first crop).

Tetramethylammonium picrate was prepared by neutralising an aqueous solution of tetramethylammonium hydroxide with an alcoholic solution of picric acid, followed by recrystallisation of the product from 70 per cent. alcohol (11 c.c. per gram, 92 per cent. recovery on first crop). The hydroxide was prepared from the bromide by reaction with silver oxide; the bromide used was obtained by recrystallising Eastman tetramethylammonium bromide twice from 95 per cent. alcohol (18 c.c. per gram, 80 per cent. recovery on first crop).

**Method.**—All of the series were carried out by a dilution method. The procedure given below is for tetrabutylammonium picrate; on account of the lower solubility of the tetramethyl salt, the initial solutions for this compound and for the mixtures were prepared in a 500 c.c. reservoir, from which about 90 c.c. were pumped into the cell by pressure of dry air saturated with ethylene chloride vapour. (The cell was, of course, previously filled with air saturated with solvent vapour.) This variation was necessary in order to avoid weighing less than 50 mg. of salt.

A sample of salt (about 100 mg., weighed to 0.02 mg.) was weighed into the cell and then about 90 c.c. of ethylene chloride were added. After the salt was dissolved, the cell cap was lifted an instant to release any excess pressure, and the solution was weighed. A correction was applied for the

<sup>9</sup> Jones and Bradshaw, *ibid.*, **55**, 1780.

<sup>10</sup> Jones and Christian, *ibid.*, 1935, **57**, 272.

<sup>11</sup> Jones and Bollinger, *ibid.*, 1931, **53**, 411.

ethylene chloride in the vapour phase (the solvent has a vapour pressure of about 0.10 atmosphere at 25° and a molecular weight of 98). No reduction to vacuum weights was made, because salt and solvent have about the same density and the weight concentration is obtained as the ratio of weights of solute and solution. In order to obtain volume concentrations, the density<sup>11</sup> of ethylene chloride, 1.2455, was used at each concentration, since the highest concentration measured was only several thousandths normal, and the concentrations of the solutions used in the comparison with theory were never greater than  $2 \times 10^{-4} N$ .

After weighing, the cell was placed in an oil bath at  $25 \pm 0.002^\circ$ , and allowed to come to temperature equilibrium, after which the resistance was measured. In order to obtain the next (more dilute) solution, a portion of the solution was removed by means of a pipette of the design shown in Fig. 1. The pipette had previously been cleaned, weighed and evacuated.

FIG. 1.—Dilution pipette.

The cap was removed and the capillary tip was placed under the surface of the solution in the cell, after which the lower stopcock was opened. After a suitable volume had been drawn into the pipette, the stopcock was closed, the pipette withdrawn from the cell and the cap replaced. Then the stopcock was reopened for a few seconds so that the entering air swept the capillary free of solvent and vapour. The weight then gave the actual weight of solution removed from the cell; a small correction was applied for the difference in density between air (for initial empty pipette weight) and air saturated with solvent (for final weight). The ethylene chloride in the vapour phase in the pipette, of course, counts as solvent removed from the cell. Next, ethylene chloride was added to the cell to bring the volume back to about 90 c.c., and after mixing, the cell was weighed and replaced in the thermostat. The above procedure eliminates errors due to evaporation.

**Sorption Effects.**—In making a series of dilutions by the method described above, it was found that the conductance values obtained for tetrabutylammonium picrate at concentrations less than  $2 \times 10^{-4} N$  were too high when compared with values calculated from points at higher concentrations. This error indicated desorption of electrolyte from the walls and electrodes of the cell, and a careful study of the effect was therefore made, using the method of Cox, Kraus and Fuoss. This consists in making up in a reservoir a series of solutions of the same nominal concentration, and adding successive portions of these to the same cell until the resistance remains the same for repeated fillings of the cell. Points at  $1$ ,  $2$  and  $4 \times 10^{-4} N$  were determined for tetrabutylammonium picrate; the experimental results are summarised in Table I. Since the points at  $2 \times 10^{-4} N$  for tetramethylammonium picrate, obtained by the dilution method, were consistent with those at higher concentration, a detailed study of desorption effects was not made for this salt. The results at  $2 \times 10^{-4} N$  indicate that  $\text{Me}_4\text{N} \cdot \text{Pi}$  is less strongly adsorbed than  $\text{Bu}_4\text{N} \cdot \text{Pi}$ .

The details of the method are readily made clear by considering the point at  $2 \times 10^{-4} N$ . Solution A was prepared by adding about 6.5 g. of a 0.0015  $N$  solution of  $\text{Bu}_4\text{N} \cdot \text{Pi}$  from a small weight buret to 450 g. ethylene chloride in a Pyrex reservoir. As the results indicate, part of the salt was

adsorbed on the walls of the reservoir. When the first portion was added to the cell, further adsorption took place; the resistance dropped with time, and, upon repeated shaking, it became steady at 206780 ohms. Successive fillings with the same solution decreased the resistance by 660 ohms or 0.32 per cent. A second solution was then prepared in the reservoir; the appropriate correction being made for the weighed residue of Solution A remaining in the reservoir. This solution showed a further net decrease of 540 ohms or 0.26 per cent. over the preceding solution. The resistance of Solution C was 470 ohms or 0.23 per cent. less than that of B, while that of Solutions D and E differed from C only within the limit of experimental error. The final value, 205150 ohms, gives 51.91 for the equivalent conductance at  $2 \times 10^{-3} N$ , which is within 0.03 per cent. of the calculated value. The net change due to adsorption on the glass walls of the cell and reservoir and on the platinum electrodes thus amounted to 0.79 per cent. at  $2 \times 10^{-3} N$ . The net change at  $1 \times 10^{-3} N$  was 0.96 per cent. and at  $4 \times 10^{-3} N$  was 0.54 per cent. Desorption produces a smaller absolute error than does adsorption because it represents a differential rather than a total effect; for this reason we were able to obtain fairly reliable data even at  $2 \times 10^{-3}$  by dilution from higher concentrations by the pipette method. (Cf. later comparison of calculated and observed values in the Discussion.)

### III. Results.

The experimental results are summarised in Tables II.-IV. Table II.(a) gives the data for tetrabutylammonium picrate; the conductance values are about 2 per cent. higher than those reported by Cox, Kraus and Fuoss, which indicates that the salt used in the previous work may have contained some tertiary salt. (The present material was more carefully purified and melted about 0.5° higher.) Series 1 and 2 were made in different cells by different observers.

The data for tetramethylammonium picrate are given in Table II.(b). The specific conductance  $\kappa$  of the saturated solution at 25° was  $2.457 \times 10^{-4}$ . By making an empirical extrapolation on a  $\log \kappa$ - $\log c$  plot (which is nearly linear in this range of concentrations), the saturation concentration was

found to be  $2.22 \times 10^{-2}$ . Our values for the conductance of this salt average about 0.3 per cent. lower than those of Walden and Busch.<sup>11</sup>

The data for the mixtures of tetrabutyl- and tetramethyl-ammonium picrate are given in Tables III. and IV.; they include one series at a mol-ratio 0.3/0.7, three at 0.5/0.5 and one at 0.7/0.3. In the first column are given total concentrations,  $c = c_{Bu} + c_{Me}$ , and in the second the corresponding specific conductances. The heading of each table,  $c_{Bu}/c_{Me}$ , gives the molar ratio of tetrabutyl- to tetramethyl-ammonium picrate in the mixture.

#### IV. Discussion.

It has been shown that the conductance of 1-1 electrolytes as a function of concentration is given at low concentrations by the equation<sup>12</sup>

$$\Lambda = \gamma(\Lambda_0 - \alpha\sqrt{c}\gamma) \quad . \quad . \quad . \quad (1)$$

where  $\gamma$  satisfies the mass action equation

$$c\gamma^2f^2/(1 - \gamma) = K \quad . \quad . \quad . \quad (2)$$

and  $f$  is given by the Debye-Hückel limiting equation<sup>13</sup>

$$-\log f = \beta\sqrt{c}\gamma \quad . \quad . \quad . \quad (3)$$

(The limiting equation is used because ions which are not near enough to count as associated ion pairs are, on a time average, far enough apart to permit the above approximation.) The symbols have the following meanings:  $\Lambda$  = equivalent conductance,  $\Lambda_0$  = limiting conductance,  $c$  = concentration,  $\gamma$  = fraction of solute unassociated,  $f$  = activity coefficient,  $\alpha$  = Onsager's mobility coefficient,<sup>14</sup>  $\beta$  = Debye and Hückel's constant, and  $K$  = the "dissociation constant," i.e., the reciprocal of the association constant. By introducing a variable  $z$ , defined by the equation

$$z = \alpha\Lambda_0^{-1/2}\sqrt{c}\Lambda \quad . \quad . \quad . \quad (4)$$

(1) may be written

$$\Lambda = \gamma\Lambda_0 F(z) \quad . \quad . \quad . \quad (5)$$

where

$$F(z) = \frac{1}{2} \cos^2 \frac{1}{2} \cos^{-1}(-3\sqrt{3}z/2) \quad . \quad . \quad . \quad (6)$$

(Values for  $F(z)$ ,  $0 \leq z \leq 0.209$  have been published in tabular form<sup>15</sup>.) Combining (2) and (5), we obtain

$$\frac{F}{\Lambda} = \frac{1}{K\Lambda_0^2} \frac{c\Lambda f^2}{F} + \frac{1}{\Lambda_0} \quad . \quad . \quad . \quad (7)$$

which reduces the conductance curve to a straight line when  $F/\Lambda$  is plotted against  $c\Lambda f^2/F$ . Equation (7) cannot apply above a critical concentration<sup>16</sup>

$$c_{\alpha} = 3.2 \times 10^{-2} D^3 \text{ at } 25^\circ \quad . \quad . \quad . \quad (8)$$

on account of higher association than pairwise; actually deviations of the order of several tenths of a per cent. appear at somewhat lower concentrations. In ethylene chloride ( $D = 10.23$ ), the critical concentration

is  $3.4 \times 10^{-4} N$ . In Fig. 2, a plot of our data for the dilute solutions of tetramethyl- and tetrabutyl-ammonium picrates is given; it will be seen that the data give straight lines as required by (7). The slope and intercept of the lines give, respectively,  $1/K\Lambda_0^2$  and  $1/\Lambda_0$ , which, in turn, evaluate  $K$  and  $\Lambda_0$ . (For details of the method of calculation, see p. 36, ref. 3.) The results are given in Table V.

TABLE V.—CONSTANTS FOR  $\text{Me}_4\text{N} \cdot \text{Pi}$  AND  $\text{Bu}_4\text{N} \cdot \text{Pi}$  IN  $\text{C}_2\text{H}_4\text{Cl}_2$ .

Salt.	Intercept.	Slope.	$K \times 10^4$ .	$\Lambda_0$ .
$\text{Me}_4\text{N} \cdot \text{Pi}$	0.013549	5.038	0.3256	73.81
$\text{Bu}_4\text{N} \cdot \text{Pi}$	0.017421	1.3337	2.2756	57.40

A comparison of calculated and observed values is shown in Tables VI and VII. In the first column are given concentrations and in the second per cent. deviations,

$$\Delta = \left( \frac{F}{\Lambda_{\text{calc.}}} - \frac{F}{\Lambda_{\text{obs.}}} \right) \cdot 100 \frac{\Lambda_{\text{calc.}}}{F}.$$

when the deviation is positive,  $\Lambda$  (obs.)  $>$   $\Lambda$  (calc.).

The data for  $\text{Me}_4\text{N} \cdot \text{Pi}$  are somewhat more self-consistent than those

FIG. 2.—Test of conductance equation (7) for tetramethyl- and tetrabutyl-ammonium picrates in ethylene chloride. Black circles are final points from Table I.

for  $\text{Bu}_4\text{N} \cdot \text{Pi}$ . The large deviations at about  $2 \times 10^{-4} N$  indicate that the theoretical equation is beginning to fail; at  $3.4 \times 10^{-4}$ , according to (8), it would be impossible to calculate the conductance by means of (5). Our value for  $\Lambda_0$ , 73.81, for  $\text{Me}_4\text{N} \cdot \text{Pi}$  is 1.5 per cent. lower than the  $\Lambda_0$  value obtained by Walden and Busch;<sup>11</sup> of this discrepancy, 0.3 per cent. is due to a difference in absolute values of specific conductance, and the remaining 1.2

per cent. is due to Walden and Busch's method of extrapolation. When mass action effects are present, an inflection point appears in the  $\Lambda \cdot \sqrt{c}$  curve at approximately

$$c_{\text{inf.}} = 0.2165 K/f^2_{\text{inf.}}$$

For  $\text{Me}_4\text{N} \cdot \text{Pi}$  in  $\text{C}_2\text{H}_4\text{Cl}_2$ ,  $c_{\text{inf.}}$  is about  $7.5 \times 10^{-6} N$ . Near the inflection region, the curve approximates linearity, and Walden and Busch simply

extrapolated from their most dilute points linearly with a slope equal to 5430, in order to obtain their value of  $\Lambda_0$ . As a matter of fact, the curve must approach  $\Lambda_0$  at  $c = 0$ , with a slope equal to 547, the Onsager coefficient, and be concave to the axis of concentration in the region between  $c = 0$  and the inflection point.

In the case of the tetrabutyl salt, the theoretical equation seems to hold to slightly higher concentrations than for the tetramethyl salt. The large deviations at  $0.9995$  and  $1.2281 \times 10^{-4} N$  are due to desorption in diluting the more concentrated solutions. At each of these points, the concentration is calculated by the product of dilution ratios from the initial concentration used in the series; when desorption occurs, the specific conductance (and hence  $\Lambda$ ) is too large, because more electrolyte (and hence ions) is actually present than is calculated from dilution ratios. The relative error due to desorption increases with dilution. The last three points of Table VII. are those which were discussed in the section on Sorption Effects. These values are independent determinations, *i.e.*, they do not depend on a product of dilution ratios as do those in the series. It will be noted that they agree well with the calculated values, which are based on the average straight line of Fig. 2 drawn through all of the points.

		1.0000	+0.07

We next consider the mixtures. As was pointed out in the introduction, two effects combine to prevent the specific conductances from being additive: mobility effects due to mixed ionic atmospheres, and the common ion effect which promotes increased association of the relatively small tetramethylammonium ion. Both effects decrease with decreasing concentration, and at zero concentration, both components have the  $\Lambda_0$  values characteristic of the pure salts. The differential mobility effect is greater the more the mobilities of the ions of like charge differ, and vanishes for the case of equal mobility of ions of like charge. In our example, the common ion effect predominates, because the total ion concentration is so small that the net mobility effect amounts to only about 4 per cent. at the highest concentration considered, and the mixed atmosphere effect is superimposed on this correction. As will be seen below, however, the effect is large enough to be observable at  $1 \times 10^{-4} N$

in ethylene chloride. At higher concentrations, the effect would, of course, be larger, but we are unable to make the theoretical calculation because no theory is yet available.

The theory for the first effect has been developed by Onsager and Fuoss; that for the second is easy to derive. Suppose we have two salts AX (methyl) and BX (butyl) with a common negative ion X'. Let  $c_1$  be the stoichiometric concentration of AX and  $K_1$  its dissociation constant, and  $c_2$  and  $K_2$  the corresponding quantities for BX. Then at a total concentration  $c$ , we have

$$c = c_1 + c_2 \quad . \quad . \quad . \quad (9)$$

$$[A^+] = \gamma_1 c_1, [B^+] = \gamma_2 c_2 \quad . \quad . \quad . \quad (10)$$

$$[A^+] + [B^+] = [X'] = c_1 \gamma_1 + c_2 \gamma_2 \quad . \quad . \quad . \quad (11)$$

$$[AX] = c_1(1 - \gamma_1), [BX] = c_2(1 - \gamma_2) \quad . \quad . \quad (12)$$

where the bracketed quantities mean the actual concentrations of the species enclosed. We then have two mass action equations to satisfy simultaneously

$$\gamma_1(c_1 \gamma_1 + c_2 \gamma_2) f^2 / (1 - \gamma_1) = K_1 \quad . \quad . \quad . \quad (13)$$

$$\gamma_2(c_2 \gamma_2 + c_1 \gamma_1) f^2 / (1 - \gamma_2) = K_2 \quad . \quad . \quad . \quad (14)$$

where the activity coefficient is given by the equation

$$-\log f = \beta \sqrt{c_1 \gamma_1 + c_2 \gamma_2} \quad . \quad . \quad . \quad (15)$$

If  $r$  denotes the ratio  $K_1/K_2$ , we have the simple relation between the  $\gamma$ 's:

$$\gamma_1(1 - \gamma_2) / \gamma_2(1 - \gamma_1) = r \quad . \quad . \quad . \quad (16)$$

If we use (16) to eliminate  $\gamma_2$  from (13) except in  $f^2$ , we obtain the cubic equation

$$\gamma_1^3 + \left( \frac{r+x}{1-r} + y \right) \gamma_1^2 - \frac{1-2r}{1-r} \gamma \gamma_1 - \frac{ry}{1-r} = 0 \quad . \quad (17)$$

where

$$x = c_2/c_1 \quad . \quad . \quad . \quad (18)$$

and

$$y = K_1/f^2 c_1 \quad . \quad . \quad . \quad (19)$$

For simplicity, this may be written

$$\gamma_1^3 + b_1 \gamma_1^2 + b_2 \gamma_1 + b_3 = 0 \quad . \quad . \quad . \quad (20)$$

Now (17) is not a pure algebraic equation, because  $\gamma_1$  appears as an exponent in  $f^2$ , nor has  $\gamma_2$  been eliminated from  $f^2$ . It is possible, however, by a series of successive approximations to solve (17) and (16) for  $\gamma_1$  and  $\gamma_2$ , given  $c_1$ ,  $c_2$ ,  $K_1$ ,  $K_2$ ,  $r$  and  $x$ . The details of this calculation will be illustrated by a numerical example.

Suppose we have a mixture of tetramethyl- and tetrabutyl-ammonium picrates for which  $x$ , the ratio of butyl to methyl, is 0.4233, and where  $c = 1.0287 \times 10^{-4}$ . For this pair of salts,  $r = 0.3256/2.2756 = 0.14308$ . From the values of the constants given in Table V., we find, by means of (1), (2) and (3), that  $\gamma = 0.8114$ ,  $f^2 = 0.6360$  for pure  $\text{Bu}_4\text{N} \cdot \text{Pi}$  at  $c = 1.0287 \times 10^{-4}$  and  $\gamma = 0.4813$ ,  $f^2 = 0.7058$  for pure  $\text{Me}_4\text{N} \cdot \text{Pi}$  at the same concentration. If we use the average <sup>17</sup> of the  $f^2$  values, 0.6709,

<sup>17</sup> A better approximation could have been obtained by interpolating for  $f^2$  linearly on a mol fraction scale, but the final values of  $\gamma_1$  and  $\gamma_2$  are, of course, independent of the initial approximations.

as a first approximation, (17) becomes

$$\gamma_1^3 + 1.3324 \gamma_1^2 - 0.5593 \gamma_1 - 0.11210 = 0,$$

which gives  $\gamma_1 = 0.4522$ . This gives  $\gamma_2 = 0.8523$  by (16), and we now calculate  $f^2$  in second approximation by (15), using these values of  $\gamma_1$  and  $\gamma_2$ . This gives  $f^2 = 0.6841$  as second approximation, and (17) becomes

$$\gamma_1^3 + 1.3195 \gamma_1^2 - 0.5485 \gamma_1 - 0.10995 = 0.$$

The root is  $\gamma_1 = 0.4488$ , which gives  $\gamma_2 = 0.8505$  and  $f^2 = 0.6848$ . Returning this value to (17) leads to  $\gamma_1 = 0.4485$ ,  $\gamma_2 = 0.8504$ , unchanged by further repetition of the process, as the fraction of tetramethyl- and tetrabutyl-ammonium picrates existing as free ions in the mixture.

In order to compute the mobility correction by the method of Onsager and Fuoss<sup>18</sup>, we need values for the single conductances. If we assume Walden's rule to hold for the picrate ion, and using Ulich's<sup>19</sup> value  $\Lambda_0(\text{Pi}')\eta = 0.268$ ,  $\Lambda_0(\text{Pi}')$  in ethylene chloride is  $34.12 = \Lambda^\circ$ , using  $\eta_{25} = 0.007853$ . Then  $\Lambda^\circ_1 = 39.69$  for  $\text{Me}_4\text{N}^+$  and  $\Lambda^\circ_2 = 23.28$  for  $\text{Bu}_4\text{N}^+$ . We then have, in Onsager and Fuoss' notation, for the matrix giving the mobility-ratios

$$\omega_{ji} = \Lambda^\circ_i / (\Lambda^\circ_i + \Lambda^\circ_j),$$

the quantity

$$(\omega_{ji}) = \begin{pmatrix} 0.5000 & 0.6303 & 0.5377 \\ 0.3697 & 0.5000 & 0.4056 \\ 0.4623 & 0.5944 & 0.5000 \end{pmatrix}$$

The  $\mu$ 's [4.7.2] have the values  $\mu_1 = c_1\gamma_1/2(c_1\gamma_1 + c_2\gamma_2) = 0.2774$ ,  $\mu_2 = 0.2226$ ,  $\mu_3 = 0.5000$ . For the matrix  $\mathbf{H}$ , with elements [4.9.9]

$$h_{ji} = \mu_i \omega_{ji} + \mu_j \omega_{ij} \delta_{ji},$$

we obtain

$$(h_{ji}) = \begin{pmatrix} 0.5909 & 0.0823 & 0.2312 \\ 0.1749 & 0.6947 & 0.2972 \\ 0.1492 & 0.0903 & 0.7395 \end{pmatrix}$$

with the invariants [4.9.5]  $I_1 = 2.0250$  and [4.9.6]  $I_2 = 1.2853$ . For operation on eigenvectors [4.9.7], [4.9.8] of  $\mathbf{H}$ ,

$$1 - H^{1/2} = 0.6432 - 0.6992 H$$

according to the proof in § 4.9 of Onsager and Fuoss' paper. In ethylene chloride, the relative mobility correction [4.7.10] due to relaxation effects is given by

$$-\Delta X_i/X = 11.693 \Gamma^{1/2} Z'_i (1 - H^{1/2})_{i0} r_{\sigma},$$

where  $\Gamma$  is total ionic concentration,  $2(c_1\gamma_1 + c_2\gamma_2)$ . We find  $\Delta X_1/X = -0.0423$ ,  $\Delta X_2/X = -0.0307$  and  $\Delta X_3/X = -0.0371$ . In pure

<sup>18</sup> The method of calculation is fairly simple from the point of view of arithmetical manipulation, but the underlying theory is somewhat too complicated to be explained in detail here. For this reason, the reader is referred to the original paper by Onsager and Fuoss for an explanation of the method and symbols; to facilitate reference, equation numbers in square brackets will be given which correspond to those used in the cited paper. The electrophoresis correction is derived in § 4.2; in §§ 4.3-4.7, the differential equations for the relaxation effect are set up and solved; and in §§ 4.8-4.10, the method of calculation is explained. In order to read § 4.3, it is necessary first to read §§ 2.1-2.5, but the material in section 3 (pp. 2704-2735) deals primarily with viscosity effects, and may be omitted by those interested only in the conductance theory.

<sup>19</sup> Ulich, *Trans. Far. Soc.*, 1927, 23, 388.

$\text{Me}_4\text{N} \cdot \text{Pi}$  or pure  $\text{Bu}_4\text{N} \cdot \text{Pi}$  at a total ionic concentration of  $1.1688 \times 10^{-4}$  the actual ionic concentration in the mixture under discussion, the relaxation correction for either ion would be 3.71 per cent. In the mixture, the correction for the tetramethyl ion is increased to 4.23 per cent., and that for the butyl decreased to 3.07 per cent.; that is, the faster ion is slowed down and the slower ion is accelerated. Multiplying  $\Lambda^\circ$ , by the appropriate  $\Delta X_i/X_i$ , we find  $\Delta\Lambda_1 = 1.677$ ,  $\Delta\Lambda_2 = 0.715$ ,  $\Delta\Lambda_3 = 1.267$  for the relaxation corrections. We also have to apply a correction

$$[89/\eta(DT)^{1/2}](c_1\gamma_1 + c_2\gamma_2)^\dagger$$

to each  $\Lambda^\circ$ , for electrophoresis [4.2.11], which amounts to 0.723 in this case. We thus obtain  $\Lambda'_1 = 37.290$ ,  $\Lambda'_2 = 21.841$  and  $\Lambda'_3 = 32.130$  as the ionic conductances for (hypothetical) complete dissociation. In order to calculate the specific conductance, we have

$$1000\kappa = c_1\gamma_1\Lambda'_1 + c_2\gamma_2\Lambda'_2 + (c_1\gamma_1 + c_2\gamma_2)\Lambda'_3 = 3.6543 \times 10^{-3} \quad (21)$$

The observed value of specific conductance at this concentration was  $3.6531 \times 10^{-3}$ , which agrees within 0.03 per cent. with the value calculated above.

If the effects of mixed ionic atmospheres are neglected, a somewhat larger value is obtained

$$\begin{aligned} 1000\kappa' &= c_1\gamma_1(\Lambda_1^\circ - 0.0371\Lambda_1^\circ - 0.723) + \\ &\quad c_2\gamma_2(\Lambda_2^\circ - 0.0371\Lambda_2^\circ - 0.723) + \\ &\quad (c_1\gamma_1 + c_2\gamma_2)(\Lambda_3^\circ - 0.0371\Lambda_3^\circ - 0.723) = 3.6578 \times 10^{-3} \end{aligned}$$

which is 0.068 per cent. larger than the correctly computed value. If we calculate the value  $\kappa''$  obtained by adding the specific conductances of each salt present alone at its actual concentration, we obtain the specific

conductance the solution would have if there were no interaction at all. For  $x = 0.4233$  and  $c = 1.0287 \times 10^{-4}$ ,  $c_1 = 0.7228 \times 10^{-4}$  and  $c_2 = 0.3059 \times 10^{-4}$ . At  $0.7228 \times 10^{-4}$  N,  $\text{Me}_4\text{N} \cdot \text{Pi}$  has a specific conductance of  $2.7177 \times 10^{-6}$ ; and at  $0.3059 \times 10^{-4}$  N,  $\text{Bu}_4\text{N} \cdot \text{Pi}$  has a specific conductance of  $1.5353 \times 10^{-6}$ , giving  $\kappa'' = 4.2530 \times 10^{-6}$ , a value 16.40 per cent. greater than the correct value. Finally, we obtain  $\kappa'''$ , the additive value by linear interpolation on a mol-ratio scale:

$$\kappa''' = \frac{x}{1+x} \kappa_{\text{Bu}} + \frac{1}{1+x} \kappa_{\text{Me}} \quad (22)$$

At  $1.0287 \times 10^{-4}$ ,  $\kappa(\text{Bu}_4\text{N} \cdot \text{Pi})$  is  $4.4347 \times 10^{-6}$  and  $\kappa(\text{Me}_4\text{N} \cdot \text{Pi})$  is  $3.4638 \times 10^{-6}$ , giving  $\kappa''' = 3.7526 \times 10^{-6}$  which is 2.62 per cent. too large.

A similar calculation has been made at each of the points in the dilute range for the mixtures given in Tables III. and IV. This calculation is summarised in Table VIII. The percentage deviation  $\Delta$  is defined as  $100 (\kappa_{\text{obs.}} - \kappa_{\text{calc.}}) / \kappa_{\text{calc.}}$ . It will be noted that the agreement is within

FIG. 3.—Percentage difference between true and linearly additive specific conductances for equimolar mixture of tetrabutyl- and tetramethyl-ammonium picrates in ethylene chloride at  $25^\circ$  as a function of concentration. Solid curve calculated, circles observed (Table VIII.).

the experimental error in every case; the observed values contain the errors in the actual measurements on the mixtures while the calculated values naturally contain, through the two  $A_0$  and  $K$  values, the sum of the experimental errors involved in the determinations on the pure salts.

The difference between the actual value of specific conductance in a mixture and the value calculated by (22), i.e., by the simplest mixture rule, is a rather interesting function of concentration and mol-ratio. In Fig. 3, the solid curve is the calculated value of  $100 (\kappa''' - \kappa) / \kappa$  for an equimolar mixture ( $x = 1$ ), plotted against concentration, and the circles represent the experimentally determined values. At zero concentration, where there is no association,

$$\lim \kappa / c = \lim \kappa''' / c \quad (23)$$

It can easily be shown that

$$\left(\frac{d \text{ } 1000 \kappa}{dc}\right)_{c=0} = \frac{A_1^\circ + A_2^\circ}{1+x} + \frac{x(A_2^\circ + A_3^\circ)}{1+x} \quad (24)$$

and that

$$\left(\frac{d(\kappa''' - \kappa)/\kappa}{dc}\right)_{c=0} = 0. \quad (25)$$

If specific conductance at a fixed concentration is plotted against mol fraction, a curve is obtained which is convex towards the axis of mol fraction. The line joining the end points represents  $\kappa'''$ . At high concentrations,  $\kappa(\text{Bu}) > \kappa(\text{Me})$  on account of the higher dissociation of the butyl salt, while at low concentrations, where dissociation is nearly complete,  $\kappa(\text{Bu}) < \kappa(\text{Me})$ , because the  $\text{Me}_4\text{N}^+$  ion has a greater mobility than the  $\text{Bu}_4\text{N}^+$  ion. The per cent. difference between  $\kappa$  and  $\kappa'''$  has a maximum value which is at about 70 per cent.  $\text{Me}_4\text{N}^+\text{Pi}$ ; 30 per cent.  $\text{Bu}_4\text{N}^+\text{Pi}$  at  $10^{-4} N$ , and which shifts with concentration. It is possible to derive the corresponding equation, but since it is quite complicated, and does not contain much in the way of new information, it will not be discussed here. At the concentration where  $\kappa(\text{Bu}) = \kappa(\text{Me})$ , the conductance curves for the pure components cross on a  $A - \sqrt{c}$  plot. At this concentration, the equation

$$\frac{\gamma_{\text{Me}} F(z_{\text{Me}})}{\gamma_{\text{Bu}} F(z_{\text{Bu}})} = \frac{A_0(\text{Bu})}{A_0(\text{Me})} \quad (26)$$

must be satisfied. (Here  $F(x)$  is the function specified in Equation (6).) The curves cross at  $c = 2.10 \times 10^{-5}$ , which gives 0.7783 for the left-hand side of (26). From the values of the limiting conductances obtained by extrapolation on a  $F/A - cA^2/F$  plot, we find for the right-hand side  $57.40/73.81 = 0.7777$ . The agreement is within 0.1 per cent. which is within the error of locating the concentration by graphical interpolation on the  $A - \sqrt{c}$  plots.

### Summary.

An improved technique for determining conductance of solutions in volatile solvents is described. Relative values, self-consistent to several hundredths of a per cent were obtained.

The conductance of tetrabutylammonium picrate, of tetramethylammonium picrate and of various mixtures of these salts in ethylene chloride have been determined. Up to about  $10^{-4} N$ , conductance values for the mixtures, calculated from the constants  $A_0$  and  $K$  of the pure salts by an extension of the association theory to mixtures, agree with the observed values within the experimental error of about 0.1 per cent.

# ELECTRON DIFFRACTION ANALYSIS OF THE ORIENTATION OF THE MOLECULES OF LUBRICATING OILS.

BY L. T. ANDREW, A.R.C.S., B.Sc.

*Received 23rd December, 1935.*

The object of lubrication is the reduction of friction and there are two main methods of achieving this end. It has been shown by the experiments of Tower<sup>1</sup> and the theoretical investigation of his results by Osbourne Reynolds<sup>2</sup> that a well-lubricated journal or shaft becomes automatically separated from its bearing by a film of liquid oil under pressure when it is rotating at normal speeds, and the frictional resistance is then entirely due to the viscosity of the oil. This type of lubrication is known as "liquid film" or "viscous lubrication."

However, in many cases, it is impossible to design the bearings of any machine so that they shall automatically maintain a thick film of oil between the contacting surfaces. Under these circumstances, when the solid surfaces actually rub against one another, the efficiency of an oil as a lubricant is found to depend no longer upon the viscosity but upon a new property of the lubricant often termed its "oiliness." This type of lubrication is known as "solid film" or "boundary" lubrication.

In boundary lubrication, the lubricating film, though excessively thin, may be several molecules thick and it has been shown that oiliness is an expression of the fact that the molecules of an efficient lubricant become oriented on the bearing surfaces, producing films which have a very low coefficient of friction when the bearing surfaces are in contact.

Determinations of the viscosity, specific gravity, volatility, flash point, etc., give valuable information regarding the performance of a lubricant. None of these tests, unfortunately, measure the degree of oiliness upon which the reduction of friction at low speeds and under high pressures depends. This property has, hitherto, been only measured by friction-testing machines.

Since the orientation of the molecules of long-chain carbon compounds can be detected from the electron diffraction patterns obtained by reflecting a beam of electrons from a film of the compound, an attempt was made to arrange a number of oils in an order of *decreasing* degree of orientation by the Electron Diffraction method, and then to compare this order with their efficiencies as boundary lubricants as found in practice.

## Method.

Specimens of the various oils were spread out in thin films upon metal backings and inserted in an Electron Diffraction apparatus similar in design to that described by Professor G. P. Thomson.<sup>3</sup> A fine beam of electrons was passed from the discharge tube, through two small pin-holes

<sup>1</sup> Tower, *Proc. Inst. Mech. Eng.*, 1883, 632; 1884, 29; 1885, 58; 1888, 173; 1891, 111.

<sup>2</sup> *Phil. Trans.*, 1886, 157.

<sup>3</sup> G. P. Thomson and Fraser, *Proc. Roy. Soc.*, 1930, 128A, 641.

in the anode, and was incident at a small grazing angle on the specimen. The energy of the electrons used was about 30,000 volts.

### Preparation of Films.

Thick films of the oils were prepared by allowing a drop of the lubricant to spread over the surface of the backing when the latter was placed on a level surface.

Very thin films were prepared by rubbing the backing, which had been smeared previously with a little of the oil under test, with soft tissue paper until a thin uniform film was obtained. This method was employed by Murison.<sup>4</sup>

Only rough estimates of the thickness of the films used can be given. In the apparatus, the thicker films tended to flow to one end of the specimen. The thickness of these films at the point where they were struck by the electron beam, was probably of the order 0.02-0.05 cm. and in exceptional cases in which oils were superimposed one upon the other, the thickness may have reached an upper limit of 0.1 cm.

Some films were too thin to show interference colours and occasionally in the case of films on copper oxide backings, the ring pattern of the oxide was obtained with the oil pattern superimposed upon it. From the penetrating power of the electron beam, these films must have been about 100 Å. in thickness. In all probability, the length of the chain carbon compounds present in the samples would be 40 Å. and might be very much more. Thus it is seen that in the case of thin films of the lubricant, conditions approaching boundary lubrication—monomolecular layers—were obtained.

The backing generally used was either a copper block about 1 cm. square polished on 0000 emery paper or a similar surface oxidised by heating. Similar blocks of lead, silver, nickel, steel and iron were also employed in the investigation of the effect of the backing upon the degree of orientation of the molecules of the lubricant.

### Types of Pattern.

The various types of pattern obtained by the reflection of a beam of fast electrons from long-chain compounds have been accounted for, both theoretically and practically, by Murison. In this work it is only necessary to consider three:—

(a) Diffuse Rings or No Pattern, indicating a random arrangement of the molecules. (Figs. 1 and 2.)

(b) Diffuse Rings with one or more spots appearing on the second ring, indicating some orientation of the molecules. (Figs. 3 and 4.)

(c) A straight line pattern with spots on the lines—the "grease pattern," indicating the complete orientation of the molecules. (Fig. 5.)

Pattern (c) is given by substances such as vaseline, paraffin wax, picein, etc.: hence the term "grease pattern." If the long-chain molecules in a substance are all arranged parallel to each other and normal to the free surface, but otherwise have a random distribution, then each molecule will act as a scattering centre independent of the others, and it is seen the effects of the various molecules will be additive. From such considerations, Murison showed that the directions of maximum intensity of the radiation scattered by the carbon atoms lie on cones with the molecule as axis. If the incident radiation is almost normal to the molecules, the angles of the cones are very large for the earlier orders and the curves cut the photographic plate in straight lines. The spots on the lines (Fig. 5) are explained as due to reflection from planes formed by carbon atoms as the molecules become packed closely together. The strong side spots on the second order line of the pattern were shown by Murison to arise from the 110 plane in the hydrocarbon structure with a spacing of 4.17 Å. The

*See page 618.*

more intense central spot, which always appears with the above side spots, is due to reflection from carbon atoms arranged in planes parallel to the surface, the distance between consecutive atoms in the molecule measured along the chain axis being 1.27 Å. The spots from these planes will lie in the plane of incidence on the even-order lines and the more regular the packing of the molecules, the more numerous will be the spots appearing and, correspondingly, the less intense will be the lines.

Pattern (b) represents an intermediate stage between the random arrangement of the molecules of pattern (a) and their complete orientation as in pattern (c). The spots which occur on the diffuse rings are the more intense ones of pattern (c). In most cases only the central spot on the second order line is obtained. It is conceivable that pattern (b) may represent a thermal equilibrium position of orientation, the molecules, impinging on the surface of the backing and becoming oriented will tend to evaporate off into the overlying fluid, if the field of force at the interface is not sufficiently strong. The number of molecules oriented in the steady state—i.e., when the number of molecules meeting the surface of the backing and becoming oriented is equal to the number of oriented molecules leaving the interface,—will depend upon the type of molecule, the fields of force at the surface and the temperature. In pattern (a), these are such as to give practically no orientation in the steady state.

Murison has suggested that, in the case of a thin film, as a result of irregularities in the surface of the backing, some parts are only a few molecules thick, and here the orientation extends to the free surface. In other places, the film is so much thicker that the orientation, beginning at the solid-liquid interface, is gradually destroyed by the heat motions before the liquid-gas interface is reached. The former region gives rise to the spots and the latter to the blurred rings.

## Experimental Results.

The experiments were carried out with two sets of lubricating oils.

The first set consisted of some fourteen samples, all mineral oils except for one sample which was a vegetable oil containing 97 per cent. castor oil. Two of the mineral oils—Wakefields XXL and Aero Shell—contained about 6 per cent. fatty oil.

A number of specimens of each sample were prepared on the same type of backing and diffraction pictures obtained. This was necessary owing to the uncertainty in the thickness of the films. From the results an order of decreasing degree of orientation of molecule with the backing used could be deduced.

It is well known that many lubricants, when exposed to the air, take up oxygen and become thick—a process technically spoken of as "gumming." This change in viscosity may be scarcely appreciable when the liquid is kept in bulk, but when it is spread over a bearing as a thin film exposed to the air it may rapidly become a sticky mass and cease to lubricate.

This ready oxidation of a lubricant is a serious disadvantage, especially as the running temperature of bearings in machinery often reaches high values; thus this often becomes the crucial test for a lubricating oil.

The Electron Diffraction method provides a very sensitive test for any oxidation tendencies. It was found that specimens of many samples showed a degree of orientation of their molecules which increased with the time for which they were kept in the apparatus under a fairly high vacuum. At first, it was suspected that tap-grease vapour was condensing on the specimen in the apparatus. As tap-grease shows a "grease" pattern when prepared in thin film, if an oriented layer of the tap-grease formed on the surface of the oil under test, an increased orientation would be observed. If the tap-grease only dissolved in the oil, the tendency of the molecules of the mixture to orientate would be greater than before. This was demonstrated by experiments made to investigate the effect of adding an oil or

solid grease, etc., the molecules of which were known to orientate strongly, to a sample of lubricant showing no orientation. It was found that the presence of a very small percentage of the orienting substance was sufficient to ensure that the mixture should show strong molecular orientation independent of the thickness of the film prepared. A second possible explanation of this time effect was that some lighter constituents of the lubricants were evaporating off leaving the longer chain compounds behind. As it has been observed by Hardy<sup>3</sup> that orientation is more pronounced the longer the molecule, due to the greater lateral adhesion between the chains, this again would account for the observed increase in orientation.

That neither of these explanations was correct was demonstrated by the fact that the phenomenon was only shown by some oil samples, whereas, were the effect due to contamination, presumably it would have been shown by specimens of the majority of the lubricants; and, again, it was found that the same changes of pattern were even more pronounced if the specimens, instead of being kept under vacuum, were stored in dust-free air for the same time. Under reduced pressure, any evaporation from the specimen would be greatly accelerated.

The most noticeable instance of this phenomenon was observed with an oil which had been obtained by a "cracking" or destructive distillation process, and which was known to oxidise readily. The diffraction photographs showed the transformation from pattern (a) or (b) to the complete grease pattern (c) within a few hours independent of the thickness of the film used. This suggests that the surface layer of the lubricant becomes oxidised, and this oxidised layer orients itself on the surface of the oil giving the pattern (c). It is conceivable that this surface layer, in the case of a thick film of an oil which oxidises strongly may be several molecules thick.

Although these observations are made under a normal vacuum in the apparatus, it must be realised that in general there is still a small quantity of air, and hence oxygen, present, accounting for the oxidation observed.

It was found also with the "cracked" oil that on keeping a thick specimen in a very high vacuum, no increase of orientation was observed over a period of some 24 hours. However, on increasing the pressure within the apparatus to atmospheric for a few hours, orientation became apparent and a complete grease pattern was obtained, showing that the very low pressure prohibited or greatly reduced the speed of any change.

In many cases it may be that the oxidation of the unsaturated hydrocarbons present in the lubricating oils proceeds in stages. Although there is some uncertainty as to whether these unsaturated compounds are open-chain, polynuclear or naphthenic, it is conceivable that, owing to the splitting of double or more complicated bonds in the oxidation process, there may be a tendency for one end of the molecule to become loaded with oxygen atoms before the other. As shown by Hardy's work on the normal paraffins and related acids and alcohols, the addition of an  $-\text{OH}$  or  $-\text{COOH}$  group to the chain produces a remarkable increase in the lubricating power of the chain compound. This was explained by Langmuir by considering the chains as rods loaded at one end with the  $-\text{OH}$  or  $-\text{COOH}$  groups; as the rods come into contact with a solid surface, those incident upon it with their loaded end first tend to adhere for a much longer period than those meeting it with their unloaded ends. In this state of dynamic equilibrium, there are far more rods adhering by their loaded ends at any instant, and it follows that the molecular orientation will be more pronounced for the acid or alcohol than for the normal paraffin.

If the unsaturated molecules in the oil become loaded at one end with oxygen atoms on exposure to the atmosphere, an increased molecular orientation, as observed in these experiments, would be expected. Thus, after slight oxidation, it may be found that certain oils will act as more efficient lubricants owing to this increased molecular orientation; but, in

<sup>3</sup> Hardy, *Proc. Roy. Soc.*, 1923, 108A.

practice, this fact can only be exploited if the lubricant shows no further tendencies to react with atmospheric oxygen under normal running conditions. For, as the oxidation progresses, a stage will be reached when rapid polymerisation takes place with subsequent transformation of the chains into rings, and the formation of complicated gummy substances. The following experiment illustrates the above conclusions: A sample of the "cracked" oil previously mentioned was heated for 6 hours at a temperature of  $200^{\circ}\text{C}$ . in a test tube. At this stage, a thin film still showed an increasing orientation with time, showing that oxidation was by no means complete. The oil was now spread out in a thin film upon the surface of a large sheet of plate glass and kept in a warm atmosphere, free from dust, etc., for several days. The exposing of a large surface of oil to the oxygen in the air enabled further oxidation to proceed readily. At the conclusion of this treatment, a specimen prepared showed no orientation of its molecules on immediate preparation and no tendency for an increase in the degree of orientation with time.

For naphthenic compounds, it must be remembered that the series with which we are here concerned— $\text{C}_n\text{H}_{2n-10}$ , for example, present in Russian oils—are very much more unsaturated than the commoner series  $\text{C}_n\text{H}_{2n}$ , etc., whose properties are well-known. It seems probable that there may be chains formed on the rings, and these may be the deciding factor in the lubricating quality of the compound. A similar process to that suggested above would eventually result in these chains being absorbed into further complicated rings by polymerisation. It is well recognised that, in general, unsaturated ring compounds are very poor lubricants, so that little molecular orientation would be expected from these gummy polymers of extremely complicated structure and high molecular weight. Such a process as this would account for the lack of molecular orientation observed when an oil is kept for a long period exposed to the atmosphere before testing it, whether its unsaturated constituents be of the open-chain or ring categories.

### Analysis of Experimental Results (Table I.).

The most efficient boundary lubricants will be the oils showing a maximum degree of orientation of their molecules when prepared in thin films, and little or no further oxidation tendencies.

Amongst these we may select the mineral oils to which have been added a small percentage of fatty oil to increase their "oiliness," and also the two mineral oils specially prepared, one by Duckham, the other by the Silvertown Lubricants Limited. Both these oils are highly refined mineral oils, containing no antioxidants or dopes at all. The castor oil specimen should also be an efficient boundary lubricant owing to its property of strong molecular orientation, but its tendency to oxidise rapidly suggests that this efficiency would quickly diminish.

After the above must be classed the Russian oil group. In general, these oils, while showing only feeble orientation of their molecules, are unaffected by atmospheric oxygen, and would thus form useful lubricants for bearings which have to run for long periods unattended. The Californian and thin Pennsylvanian oils might also be included here.

The Texan oil and the "cracked" Mineral oil G, would act as very poor boundary lubricants owing to their serious gumming tendencies.

The Pennsylvanian cylinder oil is not included in the above classification, as the effect upon the orientation of the molecules of keeping a specimen of the oil was unobservable.

It was also observed that the molecular orientation of the lubricants in thin films had little relation to their respective viscosity. For example, a thin film of Aero Shell (Spec. N<sub>4</sub>) showed less molecular orientation than the Russian oil B<sub>2</sub>, although it was far more viscous. Oils of approximately equal viscosities also showed large discrepancies in orientating properties.

TABLE I.—EXPERIMENTAL OBSERVATIONS.

Oil.	Type.	Specific Gravity.	Molecular Orientation.	Effect of Time on Orientation.
A <sub>1</sub>	Mineral, Russian.	0.915	Very slight: trace of spot on second ring occasionally obtained with thin films.	Slight increase: a ring pattern (a) showed a spot (pattern b) after 3 days, but no tendency to give grease pattern on further keeping.
B <sub>1</sub>	Mineral, Russian.	0.910	Some orientation: spot on second ring pattern (b) obtained strongly with thin films.	Well-marked increase: after 30 days, complete grease pattern obtained. Some increase in orientation noted within 24 hours.
C <sub>1</sub>	Mineral, Russian.	0.905	Very slight: trace of spot on second ring occasionally obtained with thin films.	None: after 8 days, no increase in orientation observed. Oil has tendency to evaporate.
D <sub>1</sub>	Mineral, Russian.	0.896	No orientation at all.	None: no increase in orientation on keeping thin film specimen 6 days.
E <sub>1</sub>	Mineral, Californian.	0.936	No orientation at all.	No increase in orientation on keeping specimen 36 days in air. Tendency of oil to evaporate adds to the difficulty of observation.
F <sub>1</sub>	Mineral, Texan.	0.940	Slight: approximately one thin film specimen in three showed spot on second ring.	Very marked increase: complete grease pattern obtained on keeping specimen 7 days in air.
G <sub>1</sub>	Mineral, cracked.	0.916	Some orientation: majority of specimens prepared showed the spot on the second ring; some gave grease pattern.	Very marked increase: grease pattern obtained from all specimens, independent of thickness, within a few hours.
H <sub>1</sub>	Mineral, Pennsylvanian (thin).	0.865	No orientation at all.	Slight increase: spot obtained on second ring after 13 days but no tendency to give grease pattern on further keeping.
I <sub>1</sub>	Mineral, Pennsylvanian (cylinder).	0.885	Complete orientation shown by all specimens.	Unobservable as grease pattern always initially observed.
J <sub>1</sub>	Vegetable (97 per cent. Castor Oil). Mobiloil R.	—	Complete orientation generally shown by thin films: always some orientation obtained.	Well marked: thin film showing spot orientation (pattern b) gives a grease pattern after 3 days. Thicker film develops spot orientation from random arrangement within 6 days.
K <sub>1</sub>	Mineral + 6 per cent. fatty oil. Wakefield XXL.	—	Complete orientation generally shown by thin films: always some orientation obtained.	Extremely slight: spot orientation (pattern b) given by a specimen showed little tendency to improve during 21 days in air.
L <sub>1</sub>	Mineral, Spec. No. DTD 109 (Duckham's).	—	Some orientation: all specimens showed spot on second ring (pattern b).	None: thin film kept 27 days showed no increase in orientation of molecules. Thick film shows no orientation at all after 6 days in air.
M <sub>1</sub>	Mineral, Spec. No. DTD 109 (Silvertown).	—	Some orientation: all specimens gave patterns showing at least one spot on the second ring.	Slight: thicker film gave spot on second ring on keeping 6 days, but no further improvement after another 8 days in air.
N <sub>1</sub>	Mineral + 6 per cent. fatty oil. Aero shell.	—	Slight: about half the specimens gave patterns showing spot on second ring. Thick films gave little orientation at all. Oil has tendency to evaporate.	Marked increase: thin film specimen giving pattern showing spot on second ring, showed complete orientation after 14 days in air.

With one or two exceptions, the results of the investigation of the lubricating properties of this set of oils are in good agreement with the results obtained in practice. In practice the oil  $E_2$  was found to oxidise more seriously than the members of the Russian group. In the Electron Diffraction analysis, no oxidation of  $E_2$  was observed, although its tendency to evaporate may have masked the observation of an increased orientation with time.

The second set of samples which were mainly commercial products, was found far inferior to the first set as regards orientation of molecules. However, the main conclusions drawn from the previous observations were further supported. One specimen, a motor oil of unknown origin which had proved unsatisfactory in practice, was found to show a very marked increase in molecular orientation on keeping. This oxidation was probably the cause of its inefficiency. Two specimens of Mobiloil BB (not clearosol treated) were tested. One was an unused sample, the other a sample which had been employed in a friction machine for 50 hours, during which period it had been oxidised by air at  $160^\circ \text{C}$ . The former showed an increasing orientation with time, the latter not so, supporting the earlier observations, since in all probability the used sample was completely oxidised after the above treatment.

Once again the agreement between the Electron Diffraction analysis and the results obtained by friction machine tests was very good. It is found easy to pick out the inefficient lubricants by the Electron Diffraction method, but, owing to its entirely qualitative nature, very difficult to differentiate between specimens which are approximately of equal efficiency.

### Presence of Wax.

The addition of a very small quantity of a strongly orientating substance to a mineral lubricating oil was found to result in a mixture which always showed far stronger molecular orientation than did the lubricating oil alone. It was found that on adding a film of oil which showed no molecular orientation to a film or layer of grease showing complete orientation, the oil took up the grease and formed, in general, a homogeneous liquid mixture, which still showed strong molecular orientation. This was found to be so independent of the amount of liquid oil which was added to the grease, as previously explained.

In particular, it was found that the addition of a very small quantity of paraffin wax to a lubricating oil resulted in a marked increase in the resulting molecular orientation. This fact suggested that the molecular orientation of oils known to contain paraffin waxes, was due to the wax content. To test this view, two samples of oil were obtained, one of which was known to contain a very small percentage of paraffin wax, and the other the same oil with the wax removed by treatment with acetone. It was found that spot orientation (pattern *b*) could be obtained with the first when spread in a thin film on appropriate backings, but that no orientation at all could be obtained from the specimen from which the wax had been removed. These experiments seem to confirm the above conclusion.

### Discussion.

The constituents of the lubricating fractions of mineral oils consist chiefly of compounds of the general formulæ  $C_nH_{2n-2}$  to  $C_nH_{2n-4}$ . Of the above hydrocarbons, those of the general formula  $C_nH_{2n-4}$  are recognised as giving the lowest coefficient of friction as well as the greatest durability. This is illustrated to some extent in the case of the two Pennsylvanian oil samples tested. The heavier oil, which contains a greater proportion of compounds of the general formulæ  $C_nH_{2n-4}$  and  $C_nH_{2n-6}$ , was found much superior as regards molecular orientation to the lighter oil, the chief constituents of which are compounds of the general formulæ  $C_nH_{2n-4}$  and  $C_nH_{2n-6}$ .

The Texan petroleum (density 0.94-0.96) are, in general, more unsaturated than the Russian petroleum, due to the presence of compounds of the general formula  $C_nH_{2n-12}$ . Such compounds would be expected to possess great chemical activity. Prolonged reaction with atmospheric oxygen results in the formation of oxidation products which are, in general, gummy substances and useless for lubricating purposes. Such an oxidation was actually observed with the specimen of Texan oil under test.

The effect of the addition of a small percentage (2 per cent.) of oleic acid to a mineral lubricating oil seemed to be to reduce slightly the rate of increase of molecular orientation on keeping the specimen in air.

The explanation of the occasional lack of agreement between the results obtained in the present investigation and in practice, may be in the fact that the oils are tested under rather different conditions of temperature in the two cases. In modern machinery, under boundary lubrication conditions, the temperature of the bearing is often  $100^{\circ}$ - $150^{\circ}$  C., and may be higher, whereas, in the electron diffraction experiments the tests are carried out at room temperatures.

### Effect of the Backing.

The frictional resistance of a bearing is due to what may be termed the 'unctuous' nature of its surface; for each metal tested for slipperiness against itself, without any lubricant, gives a distinctive coefficient of static or boundary friction.

In order to test whether the backing upon which an oil film was prepared influenced in any way the degree of orientation of the molecules, a number of blocks of different substances, mainly metals, was used. All the blocks were polished on 000 emery, and in every case a thin film of the same mineral lubricating oil was used as giving the most instructive indication of the orientation on the metal surface. For, in the case of an oil or grease whose molecules orientate readily, a "grease" pattern is obtained by electron diffraction independent of the backing used. On the other hand, with oil specimens which in thin films show a spot on the second ring (as did the mineral oil used in this investigation), the effect of the backing can be investigated, since, as the orientation at the oil-air interface is slight compared with that at the metal-oil interface, the possibility of the orientation of the molecules persisting to the free surface depends almost entirely upon the degree of orientation at the metal-oil interface.

TABLE II.

<i>Backing Used.</i>	<i>Experimental Observation (thin film of lubricant).</i>
Clean copper.	No orientation.
Oxidised copper ( $Cu_2O$ ).	No orientation.
Steel.	Orientation (spot on second ring).
Tarnished steel.	No orientation.
Swedish iron.	Slight orientation (spot on second ring).
Slightly oxidised, Swedish iron ( $\alpha$ - $Fe_2O_3$ ).	Orientation (spot on second ring).
Nickel.	No orientation.
Lead.	No orientation.
German silver.	Slight orientation (spot on second ring).

Thus from the results shown in Table II., it is observed that iron, steel and german silver are the more suitable for use with the mineral oil lubricant in question than the other materials tried: thus iron, steel and german silver are the more "unctuous".

Experiments with pure substances as lubricants have shown that the more "unctuous" the metal forming a bearing, the lower will be the friction obtained with any particular lubricant. Thus iron, steel and german silver should be efficient bearing materials. In practice the best materials are mild steel, cast iron, and the white metals.

### Corrosion of Metals by Oils.

A number of experiments were carried out upon the corrosion of metals by oils, an attempt being made to identify the nature of the corrosion products by Electron Diffraction.

In this investigation, the procedure was to immerse a metal surface polished on 000 emery completely in the oil to be tested in a test tube. The whole was then heated in an electric furnace to a temperature of about 250° C., the state of the surface being investigated by inserting the specimen in the apparatus after, say,  $\frac{1}{2}$  hour, 3 hours, and 12 hours. Prior to the insertion of the metal, the furnace was switched off and the whole allowed to cool to room temperature. The metal block was then removed, washed in benzene and ether to remove any residual oil on the surface, and an electron-diffraction picture taken. In this way, provided an initial picture is taken of the metal surface before the commencement of the experiment, the gradual contamination of the surface can be investigated.

A number of different metals, including copper, chromium, nickel, iron and steel were used both with a mineral and a fatty oil. It was found that after a period of 15-30 minutes heating in the oil at 250°-300° C., the initial ring pattern of the polycrystalline metal gave place to a new sharp ring pattern either of the oxide alone, or of the oxide and the metal. In the case of iron, the new pattern was of  $\alpha$ -ferric oxide ( $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>), while for nickel and chromium, rings of both oxide and metal were generally present. Copper showed a pattern of cuprous oxide (Cu<sub>2</sub>O) when the metal was heated in the vegetable olive oil, but an unidentifiable pattern when heated in a mineral oil. This substance, which was not cupric oxide, nor the third copper oxide discovered by Thomson and reinvestigated by Murison, had the following set of spacings:

$$\begin{array}{llll} 3.28 \text{ W} : & 2.41 \text{ W} : & 1.92 \text{ S} : & 1.67 \text{ S} : \\ & & (\text{unresolved doublet}). & \\ 1.26 \text{ S} : & 1.12 \text{ W} : & 0.96 \text{ M} & \end{array}$$

There is little likelihood of there being any copper rings present as the strong  $\sqrt{3}$  ring, with a spacing of 2.11, does not appear.

There was difficulty also in identifying the new pattern obtained with steel heated in a mineral oil. The patterns obtained in this case were poor and indistinct, due to much background scattering. In all probability, the pattern was due to oxides and metal together.

As in many cases the patterns of both the metal and the oxide appear, the layer of oxide must definitely be less than  $10^{-4}$  cm. thick.

On further heating the specimen in the oil and re-investigation of the surface by electron diffraction photographs, it was found that there was no further change in the ring pattern, but the background intensity increased until after a period varying from 5-10 hours for different metals, only the strongest rings of the initial pattern remained visible.

It was found that if the metal was heated in the oil for much longer periods—50-60 hours for example—the sharp ring pattern was completely suppressed and diffuse rings appeared on the plate, showing a random arrangement of molecules of impurity, greater than  $10^{-4}$  cm. in thickness, present upon the surface. If the specimen was now kept in benzene for several days, it was found that the diffuse ring pattern disappeared and the original sharp rings began to appear in the still intense background. Fig. 6 shows the initial pattern for a chromium surface and Fig. 7 the new pattern after 60 hours' heating.

Thus from these experiments we can conclude that the main cause of corrosion is the accumulation of an amorphous layer, probably of some organic substance, upon the surface of the metal. The corrosion was found to be more serious for an oil which had been used for a long period before this experiment was carried out than for the same oil previously unused. This suggests that the organic compound concerned may be some gummy

oxidation product. No marked difference was observed in the behaviour of the mineral and vegetable oils in this respect. Of the metals, chromium and nickel, in general, seemed to suffer less seriously from the corrosion effect than did the iron and steel.

### Summary.

An electron diffraction method for investigating the molecular orientation and hence the boundary lubricating properties of lubricating oils is described. The results obtained are found to be in reasonable agreement with those actually obtained in practice. In the process of the experiments, some of the commoner defects of lubricants, such as oxidation and corrosion, are also investigated.

In conclusion I would like to express my gratitude to Professor G. P. Thomson for suggesting the research, and for his kindly interest and encouragement during its progress.

## THE MECHANISM OF COAGULATION BY ULTRASONIC WAVES.

By K. SÖLLNER AND C. BONDY.

*Received 27 January, 1936.*

### 1.

When emulsions are produced by ultrasonics, their concentration quickly reaches a limiting value.<sup>1</sup> This cannot be explained by spontaneous coagulation going on in these emulsions, since it is too slow; <sup>1</sup> one is dealing with a specific coagulating action of the ultrasonics.

This coagulation is not due simply to the strong movement of the liquid when irradiated, though such an action has to be taken into account to a certain extent,<sup>2</sup> for unprotected emulsions of mercury or toluene are markedly destroyed by vehement shaking.

The following experiments show that the existence of a limiting value must be attributed to a special mechanism of coagulation; it is the interaction between the emulsifying and coagulating action of the ultrasonics which is responsible for the final concentration of the emulsion.

Since the fundamental difference between the mechanism of emulsification of mercury and that of organic liquids ("oils"),<sup>3</sup> becomes again apparent, they may be treated separately.

### 2.

In mercury emulsions the coagulation effect may readily be separated from that of emulsification: two test tubes containing 0.5 c.c. Hg + 5 c.c. H<sub>2</sub>O are irradiated till the limiting value is reached (thirty seconds and 115 mA., as strength of the current entering the secondary circuit).<sup>1</sup> In the one tube the aqueous emulsion is separated from the bulk of mercury and irradiated again for thirty seconds; the macroscopic movement of the

<sup>1</sup> C. Bondy and K. Söllner, *Trans. Faraday Soc.*, 1936, **32**, 556.

<sup>2</sup> Cf. e.g. A. Boutaric and J. Bouchard, *Bull. Chim. Soc. France*, (4), 1932, **81**, 543; cf. *Zentralblatt*, 1932, **II**, 2024.

<sup>3</sup> C. Bondy and K. Söllner, *Trans. Faraday Soc.*, 1935, **31**, 835, 843.

liquid was not nearly so strong as when the latter was shaken vehemently. As soon as the coarse particles had settled (two minutes after the irradiation was stopped), the concentration of each emulsion was determined: the one which was irradiated a second time was transparent, light grey and contained only 0.8 g. Hg per litre; the other was opaque, black and contained 5.9 g. Hg per litre.

Coagulation by ultrasonics proceeds in the aqueous phase. Emulsification, however, as has been shown,<sup>4</sup> proceeds in the surface of the bulk of the mercury, where thin films of the metal are lifted up and dispersed. Hence the amount of Hg must be sufficiently large if emulsification is to be observed at all.

The limiting value of concentration—using high energies (100 mA. and more)—is 6 g. Hg per litre, *i.e.* 30 mg. in 5 c.c. and is reached after thirty seconds irradiation. If small amounts of Hg of this order of magnitude (2 to 30 mg.) are added to 5 c.c. H<sub>2</sub>O and irradiated for thirty seconds or even much longer, practically no emulsification is observed; the aqueous phase is just slightly turbid, the opacity increasing with the amount of mercury used. Strong emulsification does not occur till 100 mg. and more of mercury are added; the emulsions are then opaque and greyish black, although less dense than those prepared in the presence of larger amounts of mercury. If small amounts of Hg (5 to 50 mg.) are added to a concentrated emulsion, which has been separated from the bulk of the metal, and these systems are irradiated under the conditions mentioned above, then the emulsions are coagulated practically as strongly as in absence of mercury in bulk.

Coagulation depends upon the volume of the aqueous phase: less mercury is coagulated, if the volume of the aqueous phase is smaller. If a given amount of Hg is irradiated in 1 c.c. H<sub>2</sub>O instead of 5 c.c., the emulsion becomes more concentrated.<sup>4</sup>

We must therefore distinguish between the locus of emulsification, a thin layer *s* at the interface between mercury and water, lying mainly in the interior of the bulk of the metal,<sup>4</sup> and the locus where only coagulation and no emulsification takes place, *i.e.* the aqueous phase of the emulsion *l*. With increasing *s* the average concentration of the emulsion increases, with increasing *l* it decreases.<sup>5</sup>

### 3.

Emulsions of toluene (and other oils) seem at first to behave quite differently. If such an emulsion (produced by ultrasonics) is separated from the bulk of toluene, and then irradiated once more for thirty seconds (or even much longer) under the same conditions, no coagulation takes place; the emulsion has exactly the same properties as one prepared by a single irradiation. This difference in behaviour between "oil" and mercury emulsions is readily understood, when it is remembered that the mechanism of emulsification is quite different with "oils."—Here emulsification is caused by cavitations occurring at the interface of the two liquids, and there is no need for coherent masses, as with mercury, so that any small amount of toluene may be emulsified, as is proved by the following experiments.

<sup>4</sup> W. T. Richards, *J. Am. Chem. Soc.*, 1929, 51, 1724; C. Bondy and K. Söllner, *loc. cit.*, p. 843.

<sup>5</sup> *s* does not necessarily increase indefinitely with an increasing quantity of mercury. On the one hand too large a metal mass may damp the vibrations; on the other hand only those parts of the metal act as *s* where the water is driven into it, *i.e.* mainly a ring-shaped zone round the meniscus. Cf. <sup>4</sup> and H. B. Bull and K. Söllner, *Koll. Z.*, 1932, 60, 263.

As mentioned in a previous paper, 4 per cent. toluene (this being the limiting value) are emulsified in less than thirty seconds using an energy corresponding to 115 mA., *i.e.* 0.2 c.c. toluene in 5 c.c.  $H_2O$ . If different amounts of toluene (between 0.05 and 0.6 c.c.) plus 5 c.c.  $H_2O$  are irradiated with 115 mA. emulsification sets in directly; after thirty seconds the samples containing 0.2 c.c. and more of toluene are equally opaque; in those containing smaller amounts opacity decreases proportionally to the amount added. With 0.2 c.c. toluene and less no external phase (or large drops) are observed, after irradiation, as is the case with more than 0.2 c.c. toluene.<sup>6</sup> This behaviour remains the same, irrespectively of whether the liquid wets the walls of the tube. The result is substantially the same, if water is emulsified in toluene.

Under the conditions of these experiments (a few c.c.s of liquid, normal test tubes and high energies) the locus of emulsification and coagulation are identical. In order to separate them, one must change either the shape of the vessel or the energy applied.

If instead of ordinary test tubes, in which the liquid is almost entirely surrounded by the vibrating oil fountain, a long tube (*e.g.* 50 cm. long, 1 cm. wide) is used, coagulation may readily be observed: the tube is filled with a 4 per cent. toluene emulsion up to a height of 35 cm. and is dipped with its lower end into the oil fountain (energy 115 mA.). Almost immediately more or less regular, more pronouncedly whitish zones appear in the lower and middle part of the tube (Fig. 1).<sup>7</sup> In these zones the droplets of the emulsion are accumulated. They soon form larger drops which may be seen rising to the surface, if the tube is taken out of the fountain for a moment. During irradiation these larger drops are, at first, retained at the level of their formation. Shortly afterwards on growing larger they jump from one zone to the next, thus forming gradually a coherent layer of toluene on the top of the liquid. In the ranges lying between these zones of accumulation the concentration of toluene is markedly reduced. If the irradiation is extended for some minutes, the liquid in the lower and middle part of the tube becomes transparent, containing only small amounts of toluene. But the top part of the liquid to a range of 10 to 15 cm. never becomes quite clear, this range, of course, being smaller at lower energies (Fig. 1) close to the always violently moving interface water/toluene there is always a dense emulsion.

If the same experiment is done with water filling the tube to a height of 35 cm. and covered with a few drops or c.c.s of toluene, emulsification at once takes place close to the strongly agitated interface; below the latter to a range of several cms. the aqueous phase contains large amounts of dispersed toluene, the concentration being practically zero 10 or 15 cm. below the interface water/toluene. In both experiments the final stationary state after prolonged irradiation is identical.

Substantially the same results are obtained with an organic liquid heavier than water; *e.g.* in an emulsion of nitrobenzene zones of accumulation occur in the lower and middle part of the tube, (leading to a rapid decrease of concentration in these parts, which is much slower near the violently moving surface), and a range of emulsification close to the interface nitrobenzene/water at the bottom. If a few c.c.s of nitrobenzene are covered with a tall column of water, again emulsification takes place only close to the interface. If some nitrobenzene is brought on the top of a tall column of water, the latter being irradiated, the nitrobenzene is first

<sup>6</sup> Of course primary emulsification is quicker with more toluene up to a certain limit. There is a larger interface, where initial cavitation may occur. Nevertheless, with high energy as well as with small amounts of toluene the stationary state is reached in thirty seconds.—When once emulsified, the presence or absence of a surplus of "oil" has no importance at all.

<sup>7</sup> To obtain a better photograph a column of emulsion only about 14 cm. high was used here, and correspondingly a somewhat lower energy was applied. The oil fountain is to be seen at the bottom.

emulsified close to the surface water/air; emulsification stops almost entirely whilst the organic liquid is sinking through the middle part of the tube, but takes place again, as soon as the nitro-benzene reaches the bottom, where it dips into the fountain.

In this way it was possible, though not very completely, to separate the locus of coagulation from that of emulsification. Where zones of accumulation appear coagulation occurs; where their formation is prevented by vehement movement of the liquid, emulsification and coagulation counterbalance each other. Movement is specially strong close to a surface or to an interface between two liquids; it is adversely affected by too small an amount of the second liquid. Thus very favourable conditions for emulsification prevail, when the more usual test tubes and amounts of liquids are utilised.

It is obviously not the amount of energy entering the system which is decisive for the different behaviour in the locus of coagulation and that of emulsification. The main point is that zones of accumulation can be produced.

This phenomenon becomes the more conspicuous, also in short columns of liquid, if narrower tubes are used; in narrow tubes the effects of stirring and of eddies are strongly reduced. These effects are due, at the bottom of the tube, to an irregular admission of the energy transferred from the oil fountain, quite generally to irregularities of refraction and reflexion at walls and surfaces. Close to the latter such irregularities prevent the formation of well-defined, constant stationary waves, which produce the visible accumulation.

These stationary waves in the liquid are obviously the cause of the accumulation of droplets, a phenomenon identical with Kundt's dust figures.<sup>6</sup> In such a zone coagulation takes place, in part owing to the much higher concentration, in part owing to a kind of ortho-kinetic coagulation:<sup>6</sup> drops of different size moving with different velocity, thus colliding and coalescing.

These results may be confirmed by experiments with low energy. If a long tube containing a column, 30 to 35 cm. high, of a 4 per cent. toluene emulsion is dipped into an oil fountain of 40 to 50 mA., zones of accumulation appear soon, large drops are formed and rise up to the surface, and after a few minutes the aqueous phase is covered with a coherent layer of toluene. This experiment is distinguished from the one performed with higher energy only in so far as the whole process occurs much more slowly and as the zone of coagulation extends practically up to the surface, the latter being only weakly agitated. If a tall column of water covered with a layer of toluene is treated with ultrasonics of the same low energy, very slight changes occur after an irradiation of several minutes: the thin layer of water between the toluene and the glass, initially covering the glass

<sup>6</sup> It has long been known that suspended particles are driven together by stationary sound waves. (Cf. A. Kundt and O. Lehmann, *Ann. Physik.* (Poggendorff), (1874), 153, 1; K. Döring, *Ann. Physik.* (IV.), 1908, 25, 227.) Boyle and co-workers (cf. e.g. R. W. Boyle, *Science Progress*, 1928, 23, 75) have described this phenomenon with ultrasonics. A flocculation of solid particles was mentioned by R. W. Wood and A. L. Loomis (*Phil. Mag.*, (7), 1927, 4, 417) the coagulated material being driven to the surface by "radiation pressure."

N. Marinenco (*C.R.*, 1932, 194, 1824) shortly describes a similar effect due to stationary waves, after E. Newton Harvey (*Biol. Bull.*, 1931, 59, 300), had described the same for gas bubbles. A first account of our own work on this subject was given by H. Freundlich (*Technical Aspects of Emulsions*, p. 1, London, 1935).

<sup>7</sup> P. Tuorila, *Kolloidchem. Beihefte*, 1927, 24, 1, 27; G. Wiegner, *J. Soc. Chem. Indust.*, 1931, 50, 55.

surface, is emulsified in the toluene and a water layer just below the interface of the two liquids becomes also slightly turbid.

By reducing the energy still further, zones of accumulation may also be produced in short columns of liquid contained in normal test tubes,<sup>10</sup> and energy ranges may here also be readily found where upon irradiating, coagulation occurs but no emulsification.

The energy of ultrasonics must exceed a certain value in order to have an emulsifying effect upon mixtures of organic liquids and water. Below this limiting value weak ultrasonics only have a coagulating effect on oil emulsions. Thus the coagulating action may be isolated. When using high energies dispersion and coagulation cannot be separated from each other close to surfaces or interfaces, where the movement is too vehement, since cavitation is obviously favoured here, thus increasing the movement still more and making it more irregular. Coagulation may become visible in the interior of the liquid, where fairly constant zones of accumulation can be formed. In the ranges close to surfaces and interfaces, however, coagulation also proceeds, zones of accumulation being produced irregularly as to space and time; the same forces act here upon the particles as in other cases but the high local concentrations so favourable for coagulation are not attained.

All this may be confirmed by a third method of separating coagulation from emulsification. If an emulsion in a long tube is covered with a tall column of a liquid of smaller specific gravity and an external pressure is applied by means of compressed gas, cavitation, and therefore emulsification is prevented, whilst coagulation still proceeds. This latter process is again favoured by the formation of stable zones of accumulation, i.e. high concentration.

In these zones, furthermore, the coagulated material is retained, since it cannot cream up or settle down, thus forming excellent centres of coagulation for other smaller droplets. If more or less regular and stable stationary wave patterns are not formed, the coagulated material creams readily up or settles down or is, as a rule, driven to the surface by "radiation pressure."<sup>11</sup>

Now it may easily be understood that the coagulation by ultrasonics of mercury emulsions is not essentially different from that of oil emulsions; it is only somewhat simpler, the disturbing effect of cavitation being excluded. If a long tube containing a mercury emulsion is dipped into the oil fountain, regular striations of mercury soon appear on the walls of the tube, provided that the latter is lying in a position about horizontal.

As was to be expected, with mercury emulsions the disturbing influence of surfaces is not nearly so distinct: firstly cavitation cannot bring about re-emulsification of already coalesced mercury suspended in the liquid; secondly the coagulated material settles down somewhat quickly, being too heavy to be kept in suspension in the liquid by stationary waves.

Ultrasonics cause coagulation in suspensions just as in emulsions. The analogy is so obvious that it hardly needs a separate treatment. It can be shown very impressively when irradiating a very unstable suspension (e.g. that of quartz in some organic liquids). When irradiated under suitable conditions the dispersed phase is coagulated at once.

<sup>10</sup> This readily explains why, with low energies, low maximum concentrations are found. Cf. C. Bondy and K. Söllner, *loc. cit.*, p. 556, Table II. (a).

<sup>11</sup> Cf. e.g. W. R. Wood and A. L. Loomis, *loc. cit.* <sup>9</sup>.

## 4.

Clear stationary wave patterns produced by ultrasonics in a liquid may be investigated most successfully with the following device: the emulsion (or suspension) is filled into a thick-walled capillary which is slightly U-shaped in the middle; this part is dipped into the oil fountain, the two ends protruding horizontally sideways (Fig. 2). Thus one may avoid the very disturbing strong changes in concentration due to creaming up or settling down close to the meniscus. If high energies are to be applied, it is advisable to make the U-shaped part in the middle out of a thin-walled glass tube, so that more energy may be transmitted to the liquid. As the liquid may be thrown out when irradiated and as the striations are disturbed by too vehement a movement of the meniscus, the opening of the capillary may suitably be stopped with piceine, leaving a short air gap as buffer between the stopper and the meniscus. As dissolved gases are always partially driven out from saturated solutions,<sup>13</sup> it is advisable to use liquids which are not fully saturated with gas, since otherwise gas bubbles are formed, which, by jumping from one node to the next, disturb the regular arrangement of the striations or, if large, interrupt the sound transmitting column of liquid.

Such a capillary, then, is filled with an aqueous emulsion of benzene, toluene, etc., and irradiated. The stationary waves cause immediately or, with low energy, in the course of some seconds the formation of Kundt's dust figures (Fig. 3A). With increasing time of irradiation the zones of accumulation become much sharper. Under favourable conditions thin disks with a well-defined boundary seem to stand upright in the liquid. The distance between two stripes is  $\lambda/2$ ,  $\lambda$  being the wave-length calculated from the frequency and the sound-velocity in the liquid. The first stripe is found at a distance of  $\lambda/4$  from the meniscus (cf. Fig. 3A), i.e. at a node, the meniscus always being the locus of an antinode.

If exactly the same experiment is done with emulsions of nitrobenzene or mercury, or with a suspension of quartz, the first stripe lies at the meniscus itself, the next at a distance of  $\lambda/2$  from the meniscus, i.e. at the antinodes (cf. Fig. 3B). So far as these experiments have proceeded, accumulation in aqueous systems occurs at the nodes if the dispersed substance is less dense than water; and at the antinodes if it is denser than water or the aqueous solution used. The mechanism of accumulation and coagulation is obviously the same in both cases.

This phenomenon is remarkable from a theoretical point of view,<sup>13</sup> but as it does not so much concern the coagulation of emulsions, it need not be discussed here in detail.<sup>14</sup> The following experiment, however, deserves mention; in an aqueous system containing particles both denser and less dense than water, ultrasonics may separate the two kinds of particles from each other. This is shown in Fig. 3C for a mixture of an emulsion of toluene and a suspension of quartz; this figure is evidently produced by a superposition of Figs. 3A and 3B. Stripes of toluene and of quartz alternate with each other, the distance between a stripe of the one and the

<sup>13</sup> Cf. e.g. E. Newton Harvey, *loc. cit.* <sup>8</sup>, R. W. Wood and A. L. Loomis, *loc. cit.* <sup>9</sup>, and W. T. Richards and A. L. Loomis, *J. Am. Chem. Soc.*, 1927, **49**, 3086.

<sup>14</sup> Cf. e.g. L. V. King, *Proc. Roy. Soc.*, 1934, **147A**, 212.

<sup>15</sup> One may assume that the decisive factor is not the differences in specific gravities; it may be some closely related function, which takes into account also the different sound velocities. (Cf. preferably the work of R. W. Boyle and co-workers: R. W. Boyle, *Nature*, 1928, **121**, 55; *Science Progress*, 1928, **23**, 75; R. W. Boyle and D. K. Froman, *Canad. J. Res.*, 1929, **1**, 405; R. W. Boyle and T. F. Lehmann, *Physic. Rev.*, (2), 1926, **27**, 518; *Trans. Roy. Soc. Canada*, (3), 1927, **21**, 115; *Canad. J. Res.*, 1930, **3**, 491, and other papers).—For the formation of the stationary wave patterns the viscosity of the medium of dispersion and vortex motion in the latter seem to play a rôle, which can hardly be altogether neglected. Cf. E. N. da C. Andrade, *Science Progress*, 1932, **27**, I., 73.

other being  $\lambda/4$ . Toluene and quartz are readily distinguished by the fact that the former creams up, the latter settles down.<sup>16</sup>

These results also prove definitely that we are dealing with stationary waves in the liquid itself. It is possible to calculate the sound velocity in the liquid correctly from the known frequency of the waves and the wavelength determined from the distance between the stripes.

The accumulation of dispersed substance at the nodes or antinodes is strongly influenced by the size of the particles, as is shown by the following experiments: three capillaries having the same dimensions were filled with suspensions of quartz (concentration about 3 per cent.). The quartz powder had been roughly fractionated. The capillaries contained particles with diameters between 4 and 10  $\mu$ , 1 and 4  $\mu$ , and below 1  $\mu$  respectively. On irradiating with medium energy the wave patterns are formed immediately with the largest particles, the liquid between them being free from particles; with the particles of medium size it takes a few seconds for the space between the striations to become practically free of particles, many seconds for the striations to become somewhat narrow and a still longer time until the pattern looks like that in the first capillary. In the third tube zones of diminished concentration appear after several seconds, zones of a certain accumulation are to be seen after a minute, but even after thirty minutes the whole pattern is blurred. In suspensions containing particles of some tenths of a  $\mu$  the effect is still less distinct. In truly colloidal solutions with our wave-length, they have so far not been obtained at all. But if by coagulation with electrolytes large secondary particles are formed, the latter may be accumulated on irradiation.

The forces—one may call them “radiation pressure”—due to the diffraction of sound energy<sup>16</sup> by the individual particles must be considered to be the ultimate reason for the coagulation by ultrasonics. These forces invariably cause a kind of ortho-kinetic coagulation and, when stationary waves occur, build up the zones of accumulation, which for several reasons (those we already know are mentioned above) so decidedly favour coagulation.

The coagulation process was investigated under the microscope using a somewhat wider capillary. Freshly prepared oil and mercury emulsions are markedly heterodisperse. On irradiation the coarser particles are rapidly accumulated at the nodes or antinodes; the smaller particles need a much longer time. One observes how the coarser particles are accumulated in a short time, coalescing into one or several drops more or less rapidly; if irradiation goes on, the liquid between becomes clear and the large drops increase in size until they contain practically the whole of the disperse phase. Figure 4a shows this phenomenon with a toluene emulsion some minutes after irradiation was started with medium energy.<sup>17</sup> Fig. 4b after prolonged irradiation.<sup>18</sup> Substantially the same may be seen with emulsions of nitrobenzene, or other oils as well as with mercury.

The behaviour of protected emulsions depends upon their concentration and degree of stability. When weakly protected, the droplets quickly

<sup>16</sup> To show this, the photographs 3 A, B, C were taken horizontally from the side, shortly after irradiation was started with pretty low energy. The internal diameter of the capillaries was about 1 mm.

<sup>17</sup> One is dealing here with a problem somehow similar to the problem of the scattering of light by colloidal particles.

<sup>18</sup> As the toluene creams up, this photograph was taken from above. To get a better photograph a capillary with an internal diameter of about 3 mm. was used. Already here the striations are less regular than in Fig. 3 A, B, C.

<sup>19</sup> The size of the drops in Fig. 4b is due to the fact that during the prolonged irradiation “radiation pressure” has driven large drops of coagulated toluene to the end of the column of liquid, where they are retained at the nodes, uniting with the drops already present there. Accidentally, this photograph was taken from a 3 mm. tube with thinner walls.

increase in size on irradiation. Strongly protected emulsions behave like suspensions: the particles are only accumulated; when irradiation stops, they are dispersed spontaneously or on shaking.

### Summary.

1. Ultrasonic waves display a strong coagulation action in emulsions and suspensions.

"Radiation pressure" caused by diffraction of sound energy by the individual particles drives the latter to and fro, thus increasing the rate of spontaneous coagulation by a kind of orthokinetic coagulation. It accumulates the particles at the nodes (or antinodes), wherever stationary waves occur. Here rapid coagulation sets in, the orthokinetic (and spontaneous) coagulation being enormously accelerated by the high concentration at the nodal (or antinodal) zones of accumulation, the rate of coagulation by ultrasonics being mainly dependent upon the formation of the latter.

2. In aqueous mercury emulsions the locus of coagulation may be readily separated from that of emulsification: coagulation proceeding in the interior of the aqueous phase, emulsification exclusively at the interface of large bulks of metal and water.

3. In aqueous emulsions of organic liquids this separation is not so easily effected. Both coagulations and emulsification (the latter caused by cavitations), take place. At high energies close to surface and interfaces coagulation and emulsification counterbalance each other and cannot be separated. But in the interior of the liquid under suitable conditions stationary waves and zones of accumulation (and coagulation) may be observed. Emulsification needs an energy exceeding a certain limit; coagulation may therefore be called forth exclusively below this limit, as well as by preventing cavitation (and therefore emulsification) if an sufficiently high external pressure is applied.

4. Coagulation by ultrasonics in unstable suspensions is due to the same causes as in emulsions, the analogy between the two cases being very complete.

5. The rate of accumulation at nodes (or antinodes) depends strongly on the particle-size. With the wave-lengths used, it proceeds markedly and rapidly with particles having a diameter above  $1\ \mu$ . Accumulation and coagulation are practically not observed with particles of truly colloidal size.

6. In aqueous systems, particles less dense than the medium of dispersion are accumulated at the nodes, denser ones at the antinodes. Thus in a system containing particles denser and less dense than the medium of dispersion the particles of different density may be separated from each other by irradiation with ultrasonics.

Our heartiest thanks are due to Professor H. Freundlich for his very helpful criticism and advice during this work. We are also greatly indebted to Professor F. G. Donnan, F.R.S., for his generous hospitality and his interest.

# THE PHOTO-ELECTRIC MEASUREMENT OF THE ABSORPTION OF SODIUM RESONANCE RADIATION.

BY FRED FAIRBROTHER AND JAMES L. TUCK.

*Received 31st December, 1935.*

This paper is primarily an account of an investigation into the possibilities of the measurement, by a photo-electric method, of the absorption of resonance light by a metal vapour: we have applied the method so far only to the absorption of sodium resonance light, but the general method is applicable also to other metal vapours whose resonance radiation lies in a region of the spectrum which will affect a photo-cell. The immediate necessity for such measurements lay in the use of the "life-period" method of estimating the speeds of reaction between metal atoms and halogen compounds in the vapour phase.

In this estimation the metal atoms (in a carrier gas) are led through a nozzle into the reaction vessel, where they meet the vapour of the halogen compound in such amount that the whole of the metal atoms react before they can reach the walls of the reaction vessel. By suitable adjustment of the temperature of the reaction vessel and of the rate of entry of metal atoms and halogen compound (the concentration of the latter being kept uniform over the reaction zone), a stationary state of the reaction can be obtained, when the metal atoms form a kind of "flame" above the nozzle. This "flame," which throws a shadow when illuminated by the resonance radiation of the metal in question, is most dense immediately above the nozzle opening, and falls away to zero at the edges. It can be shown <sup>1, 2</sup> that if  $n$  is the number of metal atoms entering the reaction vessel in unit time,  $c$  is the concentration of halogen compound in the reaction zone, and  $N$  is the total number of uncombined metal atoms in the reaction vessel (*i.e.*, in the "flame") at a stationary state of the reaction, then the velocity constant  $k$  is given by

$$k = \frac{1}{c} \cdot \frac{n}{N},$$

or since  $N/n = \tau$  is the average "life-period" of a metal atom in the reaction vessel,

$$k = \frac{1}{\tau c}.$$

The chief experimental difficulty is clearly the measurement of  $N$ , since  $n$  and  $c$  involve only the measurement of temperatures and pressures. In the method as hitherto used, <sup>1, 2</sup> the quantity of sodium vapour in the reaction vessel at a stationary state of the particular reaction, has been calculated from photographic measurements of the absorption of sodium resonance light by the mass of sodium vapour. This photographic method is extremely laborious and slow, several days being

<sup>1</sup> Frommer and Polanyi, *Trans. Faraday Soc.*, 1934, **30**, 519.

<sup>2</sup> Fairbrother and Warhurst, *Trans. Faraday Soc.*, 1935, **31**, 987.

required for the point-by-point photometry of the photographs and the subsequent evaluation from these measurements of the total amount of sodium in a single "flame." It was suggested by Professor Polanyi (*private communication*) that an enormous increase of speed and ease of working could be secured if the mass of metal vapour could be estimated by a few, almost instantaneous, readings of a galvanometer deflection, as could be done if the total absorption could be measured photo-electrically, and the maximum density of sodium atoms in the path of the light were kept within a region where the absorption was a linear function of the concentration. This was the main object of the present work.

There were two main issues in this problem: (a) the experimental problem of the measurement of the absorption; and (b) the investigation of the limits within which the absorption in question is a linear function of the concentration of sodium atoms, *i.e.* the limits within which the manual integration of the sodium atoms can be replaced by an optical one.

As a result of these absorption measurements (which will be discussed later) and from practical considerations of apparatus dimensions and intensity of incident light, it was found necessary to limit the total absorption by a "flame" to about 5 to 10 per cent. of the pencil of light entering the reaction vessel. It should be pointed out that under usual working conditions, the "flame" covers only a part of this pencil of light. The percentage absorption of the whole pencil (which is what is measured) is therefore much less than the average absorption over the cross-section of the flame itself. To use the photo-electric method with the required accuracy, it was therefore necessary to measure the deflection of the galvanometer operated by the photo-cell to within  $\pm 0.1$  per cent. It is to be noted that in this work we are not concerned with the measurement of the absolute intensities of the light, but only with the relative changes in the intensity due to absorption by a mass of sodium vapour.

Moreover, as we have shown,<sup>2</sup> and as is to be expected on theoretical grounds, the absorption factor of the light from the high-frequency metal vapour lamp decreases as the temperature of the lamp is raised to increase the intensity of the emitted light. It was therefore necessary to strike a balance between a falling absorption and a rising intensity of the light. The optimum conditions were given by a temperature at which the lamp gave a light of fairly small intensity. The practical problem, therefore, which was one of some difficulty, was the measurement, with a high degree of precision, of a change in intensity (due to absorption) of a comparatively feeble pencil of light.

The technique of the measurement of light by photo-cells has received much attention in recent years, and the literature on the subject is voluminous. We were, however, unable to find any method described in detail which was well suited to this particular problem. Most of the well-known methods apply to fairly bright sources of light. We considered that the "time of charging of an electrometer" method, as used for feeble illuminations, was not likely to give the required openness of scale, stability of zero and mechanical robustness. We were, therefore, led to develop a combined photo-cell and direct-current amplifier unit, which could be mounted on the reaction apparatus in place of the camera used in the photographic method.

### Experimental.

The photo-cell was specially chosen to have a high insulation resistance, high sensitivity in the desired spectral region and a minimum "dark" current. These conditions were satisfied by a G.E.C. cell of vacuum type, with a rubidium oxide-on-silver cathode and with internal and external guard rings. The direct current through this cell when illuminated by the sodium lamp was far too small to be measured directly with the desired accuracy, even by a galvanometer of the highest sensitivity. It was necessary, therefore, to amplify the current passing through the cell, and the construction of a sufficiently sensitive, yet stable and robust direct current amplifier, was one of the major difficulties in this work.

A number of designs of balanced D.C. amplifiers using electrometer tetrode valves have appeared in the last few years. These have chiefly related to the expensive American F.P.54 valve: a review of the different circuits used has been given by Penick.<sup>4</sup> We have found, however, that an entirely satisfactory balanced amplifier can be constructed by using the T113 electrometer tetrode valve of the German Osram Konzern.\* The only previous publication describing the use of this valve in such a circuit appears to be that of Barth,<sup>5</sup> who used a slightly different circuit from the present one.

Since such a D.C. amplifier, or balanced valve electrometer, has many uses beyond the present one, and since suitable values for the various resistances for use with this valve (the choice of which involves some labour), do not appear to have been published, the method of balancing and the resistances actually used in the present work are given in some detail.

The starting-point in this work was a circuit described by DuBridge and Hart Brown.<sup>6</sup> This was subsequently modified in order to render it more flexible and more suitable for use with the T113 valve. The final circuit, arrived at independently, was essentially the same as the one described by Harnwell and van Voorhis,<sup>7</sup> and used by them with the F.P.54 valve and a valve developed by the Bell Telephone Laboratories, and known as Type D-96475 Electrometer Tube.

The circuit diagram and values of resistances used in the present work are shown in Fig. 1. Since the mathematical theory of similar circuits has been described previously,<sup>6,7</sup> it will not be repeated here: but it may be stated that the practical aim in selecting the resistance values is to secure that the galvanometer deflection passes through a rather flat minimum when the filament current is varied over a small range through the rated value. Harnwell and van Voorhis arrived at suitable resistance values for use with their valves, by carefully measuring the various tube derivatives and solving the appropriate equations. The rather more empirical method described below was used in the present case, and was found to be quite satisfactory.

The T113 valve has a thoriated filament, rated by the makers to take 100 m.a. at 3 volts, a space charge or inner grid round the filament, and a very highly insulated control grid between the space charge grid and the anode. After some preliminary experiments with the valve, it was decided to use the rather high control grid bias of  $-4.5$  volts, i.e. the control grid being at least  $7.5$  volts negative to the more positive end of the filament. The maximum safe anode voltage was deemed to be 9 volts to minimise the production of positive ions in the residual gas. The high control grid bias was chosen in order to stabilise the control grid current: the immediate result of such a bias, however, with the anode and the inner grid

<sup>4</sup> Penick, *Rev. Sci. Instr.*, 1935, 6, 115.

\* We are indebted to Dr. J. C. Brentano for bringing this valve to our notice.

<sup>5</sup> Barth, *Z. Physik.*, 1934, 87, 399.

<sup>7</sup> Harnwell and van Voorhis, *ibid.*, 1934, 5, 244.

at the same potential ( $\sim 9$  volts) was that the anode current was very small, most of the current being taken by the inner grid. The potential of the latter was therefore reduced to about 4.5 volts, by the inclusion of the 5000 ohm resistance  $R'_{lg}$  in the bridge network.

The bridge network was then set up as shown in Fig. 1 (with the exclusion at first of the resistance  $X$ ). The anode resistance  $R_p$  was made approximately of the same value as the dynamic resistance of the plate-filament circuit, in order to give an approximately equal ratio arm bridge. Under these conditions the four resistances of (a) the plate-filament circuit; (b) the inner grid-filament circuit, together with  $R'_{lg}$ ; (c)  $R_p$ ; and (d)  $R_{lg}$  comprise the four arms of a resistance bridge, across two corners of which the galvanometer (with its Ayrton shunt and critical damping resistance  $R_D$ ) is placed, and which is capable of being brought to balance in the usual way by the adjustment of  $R_{lg}$ .

The effect of varying the filament current by adjustment of  $R_b$ , or by a change in the E.M.F. of the battery during use, is in the first place to alter the relative values of (a) and (b), and to a smaller extent the voltage applied to the corners of the bridge. The procedure adopted, therefore,

PHOTOMETER CIRCUIT

FIG. 1.

was to balance the bridge by means of  $R_{lg}$  (i.e., bring the galvanometer deflection approximately to zero), for various values of the filament current, as shown by the meter M.A., in an endeavour to find values of the variable resistances, such that the galvanometer deflection passed through a flat minimum on variation of the filament current alone. With the values of  $R_p$ ,  $R'_{lg}$ , and  $R_{lg}$  given in Fig. 1, variations in which are limited by the operating conditions of the valve, it was found (and will, in general, be found for similar valves) that this stabilisation occurred at a filament current which was far removed from the rated value. This difficulty could be overcome most conveniently by the inclusion of a large resistance  $X$  shunted across the plate circuit. Various fixed resistances were tried in this position, the effect of several of which is shown in Fig. 2, in which galvanometer deflection is plotted against filament current. The required resistance clearly lies between 35,000 and 40,000 ohms. A resistance of 37,000 ohms was therefore constructed and resulted in stabilisation at about 99 m.a. filament current, which is close to the rated value, and at which the filament was run thereafter. The inclusion of this resistance  $X$  reduces slightly the sensitivity of the bridge, but the present form of the latter was found to be very sensitive, and ample for the purpose

required. The voltage sensitivity, using a Moll galvanometer of  $6 \times 10^{-9}$  amp./mm. was 9600 mm./volt: this corresponds to a sensitivity of 115,200 mm./volt with a galvanometer of a sensitivity of  $5 \times 10^{-10}$  amp./mm., as used by Harnwell and van Voorhis with an F.P. 54 valve, and is therefore about 5 per cent. greater than they obtained.

The fixed resistances used in the bridge circuit, and those with tappings, were made of Manganin wire wound on slotted ebonite strips. The variable resistances were of conventional type as used in radio work, with the exception of the 6-ohm fine adjustment resistances in  $R_{lg}$  and  $R_b$ :

FIG. 2.

for these, no suitable commercial type could be found which would give a sufficiently fine and smooth variation. They were therefore made in the form of spiral slide-wires, about 100 cms. in length, wound on coarse, ebonite spirals of 9 turns.

An important feature of the apparatus was the inclusion of an air-dielectric condenser  $C$ , of  $0.002 \mu F$  capacity and high insulation resistance, between the grid of the amplifier valve and earth. This

condenser, together with the grid resistor, increased the time-constant of the circuit to about 2 seconds, and therefore gave a corresponding time-average of the response of the photo-cell. This was a necessary provision in order to allow for fluctuations in a reaction "flame" when this is used as an absorbing medium. Moreover, the inclusion of this condenser rendered the circuit very insensitive to stray high-frequency fields: probably much of the final success of the apparatus, which is used within a few feet of a powerful short-wave oscillator, is due to this condenser, and to the electrical screening which is described later.

### High Resistances.

In order to amplify the current through the photo-cell, it must pass also through a high resistance  $R_g$ , the voltage drop across which is applied to the grid and filament of the amplifier valve. The construction of a suitable resistance for this purpose was almost an investigation in itself. We were unable to buy suitable commercial resistances, and after many trials, in which were tried various compositions, and also evaporated and sputtered films of platinum and gold, on glass rods, a successful resistance was finally prepared by evaporating gold on to Pyrex glass rods which were kept at a temperature of  $300^\circ C$ . Earlier experiments with sputtered and evaporated metallic films resulted in resistances which were satisfactory for a time, but whose value gradually increased on standing. This was attributed to slow changes in the structure of the film, and therefore the metal was condensed on to the support at a sufficiently high temperature to permit of the formation of a stable structure.

The method of preparation was as follows. Two 10 cm. lengths of 0.1 mm. diam. tungsten wire were twisted together with a gold wire of similar diameter. This composite wire was then wrapped with very thin tungsten wire in the form of an open spiral, and the complete assembly arranged so that it could be heated electrically in a horizontal vacuum tube. After the wire had been given a preliminary heating in vacuo to remove grease

and tungstic oxide several carefully cleaned Pyrex glass rods (about 10 cm.  $\times$  0.3 cm.), the ends of which had been previously platinised with "liquid platinum" (as used in ceramic work), were arranged in the vacuum tube, parallel to the wire. The vacuum tube was then surrounded by an electric furnace at about 300° C., and outgassed before the evaporation of the metal. The latter was carried out simply by passing a current through the composite gold-tungsten wire: the gold, on melting, ran into the spaces between the tungsten wires which formed a carrier, so that little was wasted, and the metal could be raised well above its melting-point. The same technique was used for the evaporation of platinum. After cooling, the gold-covered rods were removed and their resistances measured. As the metal film was thickest on one side, that nearest the evaporator wire, and tapered off at the edges, the resistance could easily be adjusted by scraping to fall within a desired range. After the resistance had been so adjusted, wires were tightly twisted round the platinised ends and the whole rod immersed in melted Piccin to give protection from the atmosphere, since it was found that the films gradually deteriorated on exposure to the air.

The photo-cell, electrometer valve, grid resistance and condenser, were mounted inside a vacuum-tight, earthed copper tube, with walls  $\frac{1}{4}$ -inch thick. The photo-cell was fixed with its cathode opposite a plate glass window in the side of the tube, and was screened inside the tube from stray light from the valve filament. The copper tube was evacuated to a pressure less than 1 mm. Hg, thus avoiding trouble with electrical leaks due to ionisation of the air or to deposition of atmospheric moisture or other impurities on the parts of the very sensitive grid circuit. The rest of the amplifier, including the batteries, was housed in an earthed copper box, and was switched on by the mercury contact switch S, to avoid variable switch-contact resistance. The high-frequency oscillator and the metal vapour lamp were also screened as far as practicable by enclosure in a tinned iron box with metal gauze panels for ventilation.

Using the photo-cell described above, and a grid resistance of  $2 \times 10^9$  ohms, which gave about twice the required light sensitivity, the galvanometer deflection became steady in about fifteen minutes after switching on, and thereafter there was no detectable drift of the light-spot over a period of many hours. The amplitude of the instability variations was less than 1 mm. (in 1000 mm. deflection) and averaged about 0.5 mm. These residual fluctuations are probably due to the Flicker effect of the cathode of the electrometer valve. The complete apparatus was therefore suitable for the measurement of a change in the intensity of the beam of light, with a precision of  $\pm 0.1$  per cent. of the intensity of the unabsorbed beam. The linearity of the galvanometer deflection/light intensity relation was tested by a movable light source and the application of the inverse square law, and also by an addition method using two light sources. The curve departs from linearity only to the extent of 1 or 2 per cent. Some idea of the sensitivity of the photometer may be gained from the fact that a moderately glowing cigarette end, at a distance of several feet from the photo-cell, will produce a galvanometer deflection of more than 1000 mm.

Such a stable and sensitive photometer demanded naturally an equally stable light source. The high-frequency sodium vapour lamp responds instantly to even small changes in the voltage of the anode supply to the oscillator, and at first minute variations in the commercial A.C. supply could be followed by movements of the galvanometer light spot. As it was impracticable to use accumulators for the anode battery of the oscillator, as was done for the filament battery, a rectifier and smoothing unit was constructed to give 1000 volts: this was then reduced to the 500 volts necessary for the oscillator by a series resistance and four Cossor S. 130 neon tubes arranged in series and placed in parallel across the output. This arrangement completely smoothed out any fluctuations due to variations of the A.C. mains.

The high-frequency lamp was enclosed in a large thermostatically controlled air-oven, constant to  $\pm 0.05^\circ\text{C}$ . The lamp, however, is sensitive to temperature changes of far less than this, and with such a degree of thermostatic control, the photometer galvanometer light-spot was still subject to a very regular periodic excursion of about  $\pm 12.5\text{ mm}$ , about a mean position of  $\sim 1000\text{ mm}$  deflection. The period of this variation corresponded exactly to the operation of the thermostatic cut-off, and was due to temperature changes in the lamp, caused by the heating and cooling of the oven. Since a thermostatic control sufficiently fine to eliminate this variation was impracticable, the following device was adopted. A simple beam-splitting device was constructed by arranging a plane mirror at an angle of  $45^\circ$  to the beam from the lamp, a portion of the silvering in the centre of the mirror being removed. The direct beam through the hole in the silvering, passed to the photo-cell, whilst the major portion of the light was reflected on to the surface of a Weston Photronic cell. The current

FIG. 3.

from the latter was measured by a second Moll galvanometer (high current sensitivity type), whose light-spot moved over the same scale as that of the photometer galvanometer. By suitable adjustment of the sensitivity of this second galvanometer, small variations in the intensity of the light source were made to produce the same amount of movement of the two galvanometer light-spots. Changes in the intensity of the main beam passing into the photometer were then made by observing the differences between the two galvanometer deflections. Since, under these conditions, the Photronic cell was operating at an almost constant illumination, non-linearity of the relation between the light flux and the current output of the cell did not affect the result. Moreover, in the final arrangement of the apparatus as required for reaction velocity measurements, the photometer must be at some distance from the light source and the beam of light nearly parallel, and therefore the utilisable area of the light source must be small, much smaller, in fact, than the actual flat emitting surface of the lamp. In this beam-splitting device an image of the emitting surface

of the sodium lamp is formed by a large aperture lens on the mirror, the hole in which then acts as a stop, and defines the new source, the light from which is then made parallel by another lens, and the major portion of the light from the lamp is reflected on to the Photronic cell. Thus, by the use of light which would otherwise be wasted, we are able to use the less sensitive Photronic cell as a zero device. The optical arrangement and general disposition of the apparatus is shown in Fig. 3.

The results of a number of absorption measurements are given in Figs. 4 and 5. In these measurements the direct beam through the hole in the mirror silvering passed through a cell filled with sodium vapour and contained in an air oven, and into a condensing lens in front of the

FIG. 4.

photo-cell. The sodium cell was made of Jena glass, about 3 cm. diameter, with plane ends 4.64 cm. apart, and contained a small quantity of sodium, distilled into it in vacuo. The high-frequency lamp was operated at a temperature of 210° C., and the absorption was followed almost down to the melting-point of sodium. In Fig. 4,  $I_t/I_0$  (intensity of transmitted light/intensity of incident light) is given as a function of the absorption cell temperature (the quantity actually measured), and in Fig. 5 (curve A) as a function of the number of moles of sodium per square cm. in the path of the light. The latter has been calculated from the temperature of the absorption cell and the data of Ladenburg and Thiele.<sup>8</sup> Since, however,

<sup>8</sup> Ladenburg and Thiele, *Z. physik. Chem.*, 1930, 7B, 161.

the lowest temperature investigated by these authors was  $180^{\circ}\text{C}$ ., the vapour pressures at lower temperatures were obtained by plotting their results in the form of  $\log . p$  against  $1/T$  and extrapolating: there must still exist therefore the slight uncertainty of this extrapolation.

In Fig. 5 also (curve B),  $\log . I_t/I_0$  is plotted as a function of the number of moles of sodium per square cm. in the path of the light obtained in the same way.

These absorption measurements were made in several stages, between which major adjustments to the apparatus were made, such as re-heating of the absorption cell and re-charging of the batteries in the amplifier: the various portions of the curve "fit" perfectly, and repeat measurements made common regions showed a reproducibility within  $\pm 0.1$  per cent.\*

FIG. 5.

When light is absorbed by a homogeneous coloured solution, the absorption  $\log . I_t/I_0$  is a linear function of the concentration of the absorbing material (Beer's law). We cannot, however, deduce the concentration in a system of variable absorbing density, from the *total* absorption, by this exponential relation. We therefore, as mentioned earlier in the paper, required to know the range of sodium density over which  $I_t/I_0$  was a linear function of the number of sodium atoms in the path of the light. When the results shown in Fig. 5 are plotted on a larger scale, they show that  $I_t/I_0$  is a linear function of the amount of sodium concerned, up to about

\* We should like to thank Mr. E. Warhurst for much assistance with these absorption measurements.

45 per cent. absorption, whilst Beer's law is followed only up to about 25 per cent. absorption.

We may therefore take a mass of sodium vapour of variable density, the maximum absorption by any part of which is, say,  $x$  per cent. of the light incident on that part, and calculate the total number of sodium atoms in the system on the assumption that the absorption of any region is a linear function of the mean absorption and the number of sodium atoms in that region. Our aim in the beginning was to make this maximum absorption  $x$  equal to 25 per cent. to 30 per cent. of the light, with a total absorption of 10 per cent. (These figures were arrived at from an examination of records of "flames" obtained by the photographic method.) As can be seen from curve A, however, this can be extended to nearly 45 per cent. maximum absorption.

### Summary.

1. A sensitive photo-electric photometer has been developed for the measurement of the intensity of a beam of sodium resonance light, with a precision of  $\pm 0.1$  per cent.

2. For this purpose a stable, balanced D.C. amplifier (which may also be used as a valve electrometer) has been constructed, using an Osram T113 electrometer valve.

3. The technique of making electrical resistances of very high value, by evaporating gold on to glass rods, is briefly described.

4. Some photo-electric measurements of the absorption of sodium resonance light are given, extending down almost to the melting-point of sodium.

5. It is found that  $I_t/I_0$  (intensity of transmitted light/intensity of incident light) approximates very closely to a linear function of the number of sodium atoms in the path of the light, up to about 45 per cent. absorption of the light.

6. It is also found that Beer's law is obeyed in this absorption, over a much smaller range.

In conclusion we wish to thank Prof. M. Polanyi for his advice and help throughout this work, and Messrs. Imperial Chemical Industries, Ltd., and the Department of Scientific and Industrial Research, for research grants.

## REACTIONS BETWEEN SODIUM VAPOUR AND VOLATILE POLYHALIDES. VELOCITIES AND LUMINESCENCES.<sup>1</sup>

BY W. HELLER AND M. POLANYI.

*Received 27th January, 1936.*

The diffusion method devised by H. von Hartel and M. Polanyi\* (see Fig. 1) was applied to the reactions of sodium vapour with the following substances:

<sup>1</sup> An extract of this paper was given in *Compt. rend.*, 1934, 199, 1118.

<sup>2</sup> *Z. physikal. Chem.* 1930, 11B, 97.

The list contains nearly all the completely chlorinated or brominated polyhalides which have a sufficient vapour pressure to be introduced at room temperature into the "diffusion apparatus." The present study is in the nature of a general survey in which the emphasis is on the determination of the sequence of reactivities and on the observation of a series of chemiluminescences which made their appearance while the reaction velocities were measured.

### Experimental Procedure.

Preliminary to the study of these reactions, one of the authors (W. H.), in conjunction with Dr. Kodama and Mme. Schatunowskaja, has made an extensive re-examination of the diffusion method which is to be submitted shortly to this journal.

The following were the main results of this investigation. The distribution of the halogen compound throughout the flame region in the stationary state was determined for various velocities ( $v$ ) of the "carrier gas," using different carrier gases ( $N_2$ ,  $H_2$ ) at different pressures, resulting in different values for the diffusion constant ( $\delta$ ) of the sodium vapour in the carrier

FIG. 1.—Main Features of the "Diffusion Method."—Na-vapour is carried by a flow of carrier gas into the reaction vessel, where it meets the flow of a gaseous halogen compound HI ("halogen gas"). The reaction zone is illuminated by a sodium resonance lamp (L), the sphere of sodium vapour thus made luminescent is the "flame," the diameter  $D$  of which is measured.  $D$  is estimated through a window at  $O$  by a sighting device which is adjusted successively to the upper and to the lower edge of the "flame."

gas. It was established that conditions must be so adjusted that  $v/\delta$  ( $v$  in m./sec. and  $\delta$  in cm.<sup>2</sup>/sec.) should be between  $5 \times 10^{-3}$  and  $12 \times 10^{-3}$ , since at higher values the halogen compound is "swept out" of the flame region, while at lower values the back diffusion into the nozzle falsifies the results. The conclusion was also reached that the measurement should be based on flames of large size, if possible not smaller than 3.5 cm. in diameter.

Various improvements relating to the control of the inflowing "halogen gas" stream lead to a more accurate determination of the partial pressure of the halogen gas in the reaction zone. At the same time, a more reliable estimation of the flame diameter was introduced by "end on" observation with a levelling device adjustable to the edges of the flame. The method thus improved, yields relative velocity constants of about 15 per cent. accuracy for reactions requiring not less than about 50 and not more than about 5000 collisions.

Apart from these technical developments, of which full use has been made in the present work, special provisions were made for the handling of the halogen compounds, most of which are extremely sensitive to moisture, and attack tap-grease and mercury. The purchased halogen compounds were opened in vacuo and distilled into the apparatus. The flow of halogen

gas was controlled by valves of the membrane type (Fig. 2) and the mercury in the manometers covered with sulphuric acid or paraffin oil. Owing to these technical difficulties the capillaries, by which the flow of the halogen gas is controlled, could be calibrated only for a few of the inorganic polyhalides. The flow of the other halogen gases was calculated on the assumption that the viscosity of the vapours does not differ appreciably. This was found to be true in a comparison carried out between  $\text{CCl}_4$  and  $\text{SiCl}_4$ , as well as between a large number of halogenated organic compounds. It is believed that the error caused by the assumption of equal viscosities cannot affect the sequence of reactivities as stated below.<sup>3</sup>

The reaction rates of  $\text{CCl}_4$ ,  $\text{SiCl}_4$ ,  $\text{BCl}_3$ ,  $\text{BBr}_3$ ,  $\text{TiCl}_4$  fall within the range stated previously for which we estimate the accuracy of the relative values to be about 15 per cent. The other compounds react so fast as to lie beyond the range of velocities for which the method can be used quantitatively; in these cases only the order of magnitude of the reaction rates could be established. As to the sequence of values given for this group of substances, we see no reason why the sequence of any pair of values differing by more than 30 per cent. should not be correct.

FIG. 2.—Rotation of the knob K moves the screw S vertically. This motion is transmitted through the metal vacuum-tight diaphragm D to the needle, which can thus be raised or lowered into the valve seating V. The cones C are used to connect the valve to the apparatus.

### Reaction Velocities.

The results listed in Table I. all refer to a reaction temperature of  $270^\circ$ . The partial pressure  $p_{\text{Na}}$  of sodium at the nozzle was nearly  $3 \cdot 10^{-3}$  mm.; deviations from this value were duly taken into account. The carrier gases used were  $\text{H}_2$  and  $\text{N}_2$  (the former for faster, the latter for slower reactions), and their pressures were varied from 1 mm. to 10 mm. Each reaction velocity was determined by a series of measurements on flames of different sizes; on the average five flames were measured, ranging in size from 2 cm. to 4.5 cm. The values listed in the table are interpolated for the size of 3.5 cm.

The calculation of the velocity constants is based on the formula

$$k = \frac{\left( \ln \frac{p_{\text{Na}}}{p_0} - \ln \frac{R}{r} \right)^2}{(R - r)^2} \cdot \frac{\delta}{p_{\text{H}_2}} \cdot \frac{1}{T^2}$$

<sup>3</sup> For a determination of the absolute values of reaction rates the distribution of the halogen gas throughout the flame has to be taken into account. The influence of this correction will be shown in the detailed communication on the improvements of the experimental method, where specific reference will once more be made to the case of  $\text{CCl}_4$ .

TABLE I.

Compound.	Reaction Velocity Constant $k$ (c.c. mole <sup>-1</sup> sec. <sup>-1</sup> $\times 10^{-11}$ ).	Collision Number ( $S$ ).
BCl <sub>3</sub>	4.71	1,350
CCl <sub>4</sub>	963	6.5
SiCl <sub>4</sub>	4.03	1,570

CS <sub>2</sub>	$\sim 0.306$	207,500

where  $p_N$  and  $p_0$  are the partial pressures of sodium at the centre and at the edge of the flame respectively,  $p_0$  being  $10^{-6}$  mm.;  $R$  and  $r$  are the radii of the flame and the nozzle respectively,  $r$  being 0.25 cm.;  $\delta$  is the diffusion constant of sodium vapour in the carrier gas, and was calculated for the prevailing conditions on the basis of earlier determinations<sup>4</sup> by which the values  $\delta_{H_2} = 3.14$  and  $\delta_{N_2} = 0.92$  had been obtained for atmospheric pressure, and  $643^\circ \text{K.}$ ;  $p_M$  is the partial pressure of the halogen gas in the reaction chamber and  $T$  the absolute temperature. The reaction velocity constants  $k$  are in the units of c.c./mol. sec.

The "collision numbers" ( $S$ ) also listed in the table are based on a uniform collision diameter of  $6.7 \cdot 10^{-8}$  cm. We thus obtain the relation

$$S = \frac{6.3 \times 10^{14}}{k}.$$

The molecular velocities of the halogen compounds range between 17,000 and 34,000, which are the values for  $\text{COCl}_2$  and  $\text{SiBr}_4$  respectively. This causes a variation in the collision no. of  $\pm 3$  per cent. which has been taken into account in the evaluation of  $S$ .

In the table we have grouped our results in the following way. The chlorides are listed in the sequence of their position in the periodic system of elements. Then the bromides ( $\text{BBr}_3$  and  $\text{SiBr}_4$ ) are shown in juxtaposition to the corresponding chlorides. The next section points out the effect of a change in valency of the atom to which the halogen is linked; finally, the values for  $\text{COCl}_2$ ,  $\text{CrO}_2\text{Cl}_2$  and  $\text{CS}_2$  are given.

We note in the first part of the table that there is a considerable inertia attached to the reactions of  $\text{BCl}_3$  and  $\text{SiCl}_4$ ; the inertias of  $\text{CCl}_4$ ,  $\text{TiCl}_4$ ,  $\text{PCl}_3$  and  $\text{AsCl}_3$  are noticeable; the reactions of  $\text{GeCl}_4$ ,  $\text{SnCl}_4$  and

<sup>4</sup> H. von Hartel, N. Meer and M. Polanyi, *Z. physik. Chem.* 1932, **19B**, 139.

$\text{SCl}_2$  are practically instantaneous. If we add to the data listed in the first section of the table, the fact that the reactions of sodium vapour with  $\text{Cl}_2$ ,  $\text{Br}_2$  and  $\text{I}_2$  are all instantaneous, we cannot fail to observe that the tendency for an inertia to be present falls off when we pass from the third and fourth groups to the higher groups of the system. The fact that the volatile halogenides of the second period ( $\text{HgCl}_2$ ,  $\text{CdCl}_2$ ,  $\text{ZnCl}_2$ ,  $\text{CuCl}_2$ ) all react instantaneously suggests that the inertia has its maximum in the middle groups of the periodic system, and falls off both towards lower and higher groups. This corresponds to the changes in bond strength of the halogen atoms which are highest for the middle groups of the periodic system.

The second part of the table illustrates the increase in reactivity caused by substituting Br for Cl; a rule repeatedly observed previously in the organic series. The ratio of the velocities of the Cl and Br-compounds is similar to that found in the organic series.

An increase in reactivity, corresponding to decreasing bond strength, is also found in the two cases where compounds corresponding to a higher valency stage can be compared with compounds of a lower valency stage:  $\text{SCl}_2$  reacts faster than  $\text{S}_2\text{Cl}_2$ ;  $\text{POCl}_3$  faster than  $\text{PCl}_3$ . (The oxygen atom introduced in the latter case seems to have little effect, since  $\text{COCl}_2$  does not react faster than  $\text{CCl}_4$ .)

A measure of bond strength most appropriate to our problem is given by the restoring forces of the bonds, as derived from Raman spectra. Table II. illustrates the parallelism of the "inertia" deter-

TABLE II.

Compound:	Collision Number (5).	Restoring Force Constants ( $f \times 10^{-4}$ ) between Central Atom-HI-Atom.
$\text{CCl}_4$	0.5	2.00
$\text{SiCl}_4$	1.570	2.42
$\text{TiCl}_4$	0.4	2.20
$\text{GeCl}_4$	1.3	—
$\text{SnCl}_4$	1.8	2.00
$\text{PCl}_3$	4.2	1.9
$\text{AsCl}_3$	4.3	1.4
$\text{SbCl}_3$	—	0.87
$\text{BiCl}_3$	—	0.44
$\text{CH}_3\text{Cl}$	7,100*	3.12
$\text{CH}_3\text{Cl}_2$	310*	2.94
$\text{CHCl}_3$	22*	2.47
$\text{CCl}_4$	2*	2.00
$\text{CH}_3\text{Cl}$	7,100*	3.12
$\text{CH}_3\text{Br}$	75*	2.61
$\text{CH}_3\text{I}$	1	2.15

\* These values which have been substituted for the earlier results of Hartel, Meer and Polanyi are based on new measurements of W. Heller to be published shortly.

mined by the collision number, with the restoring force constant  $f$  of the bond. Within each of the three groups,  $\text{CCl}_4 \rightarrow \text{SnCl}_4$ ,  $\text{CH}_3\text{Cl} \rightarrow \text{CCl}_4$  and  $\text{CH}_3\text{Cl} \rightarrow \text{CH}_3\text{I}$  this parallelism holds equally well.

The high restoring force attributed to the linkages in  $\text{SiCl}_4$  might appear unexpected; it is, therefore, to be noted that it is borne out by

\* K. W. F. Kohlrausch, *Der Smekal-Raman Effekt*, 1931, page 217, expresses diffidence as to the correctness of this force constant for this reason.

the heat of formation of  $\text{SiCl}_4$  which is considerably higher than that of either  $\text{CCl}_4$  or  $\text{SnCl}_4$ . We have the energies

It seems reasonable that the force which counteracts an elongation of the halogen bond should also be responsible for the chemical inertia of such reactions which lead to the splitting up of the bond. A closer consideration of the theoretical connection of force constant and chemical inertia has been given by R. A. Ogg in conjunction with one of the authors.<sup>6</sup>

### Reaction of $\text{CS}_2$ with Na-Vapour.

We found that Na-vapour reacts with  $\text{CS}_2$ -vapour. In view of the endothermicity of the process,

the observed reaction appears to be the addition

The fact that the reaction proceeds very slowly helps to confirm this view. The observed velocity constant  $k$  (Table I.) which was measured in the presence of 6 mm. of pentane used as carrier gas, is not too large to be accounted for by three-body collisions. Indeed, the reaction is slower than in the case of the analogous reaction between Na-vapour and  $\text{O}_2$  to which reference is made later.

### Chemiluminescences.

The chemiluminescence accompanying the reaction of sodium vapour with chlorine was discovered by Haber and Zisch.<sup>7</sup> When a nitrogen stream at atmospheric pressure, carrying a slight admixture of sodium vapour, was led into chlorine a slight yellow glow appeared which was found to contain exclusively the D-line of sodium.

By the use of "highly attenuated flames" this luminescence was greatly increased in intensity, and the mechanism of its origin was elucidated.<sup>8</sup> At the same time, a number of similar luminescences were discovered, accompanying the reactions of Na-vapour with the various halogens and with the volatile halogen salts of the second sub-group of the periodic system. Two examples may show the mechanism of these luminescences

<sup>6</sup> *Trans. Faraday Soc.*, 1935, **31**, 482.

<sup>7</sup> *Z. Physik*, 1922, **9**, 302.

<sup>8</sup> H. Beutler and M. Polanyi, *Z. physik. Chem.*, 1928, **133**, 3.

In both cases the final process of excitation consists in a collision of the "nascent" NaCl<sup>\*</sup>-molecule with an Na-atom. Such chemiluminescences can arise only if there is a reaction of Na-vapour which evolves at least 48.5 kCal. which is the molar excitation energy of the D-line.

A chemiluminescence differing fundamentally from these was observed<sup>9</sup> when highly attenuated sodium vapour was brought into reaction with SnCl<sub>4</sub>-vapour. The luminescence has a continuous spectrum, the origin of which is supposed to be

Since, according to this view, the luminescence arises from two particles as they undergo the process of reaction, this type (B) has been given the name of "primary chemiluminescence." The atomic mechanism which may lead to primary chemiluminescence was discussed in detail in a recent paper by R. A. Ogg and one of the authors.<sup>10</sup> An obvious condition for the occurrence of this sort of luminescence is the presence of a heat of reaction (*E*) satisfying the condition

$$E \geq Nh\nu_1$$

where  $\nu_1$  is the short-wave limit of the continuous spectrum emitted by the reaction.

A third type (C) of chemiluminescence, the mechanism of which is still unexplained, was discovered when CuCl<sub>2</sub> vapour was brought into a flame of Na + Cl<sub>2</sub>. Besides the yellow light belonging to the Na + Cl<sub>2</sub> flame, an intense green luminescence made its appearance in which the well-known CuCl-bands were recognised spectroscopically. The same luminescence also arises when CuCl<sub>2</sub> is brought into an Na + HgCl<sub>2</sub>-flame, and it was observed also when CuCl<sub>2</sub> was introduced into a stream of atomic hydrogen reacting with chlorine; it is distinctly observable in the gas phase when chlorine attacks metallic aluminium in the presence of CuCl<sub>2</sub> vapour.<sup>11</sup> The peculiar feature of these latter luminescences lies in the fact that although no emission of light accompanies the reaction between CuCl<sub>2</sub> with either Na-vapour or H-atoms or metallic aluminium, the presence of another body, such as Cl<sub>2</sub> or HgCl<sub>2</sub> reacting simultaneously with these substances gives rise to the luminescence.

The chemiluminescences newly observed in connection with the reactions of the inorganic polyhalides seem to belong partly to type A or B; another group which made its appearance only when O<sub>2</sub> was added to the flame, shows some similarity to type C, but may prove to represent an altogether new type.

Table III. presents the observations on chemiluminescence. With (CCl<sub>4</sub>, SiCl<sub>4</sub>, AsCl<sub>3</sub> and CS<sub>2</sub>, no luminescence was observed; accompanying the reaction of TiCl<sub>4</sub> there sometimes appeared a faint glow, but the existence of this luminescence could not be definitely established. Clearly visible luminescences were present in the reactions of BCl<sub>3</sub>, BBr<sub>3</sub>, SiBr<sub>4</sub>, GeCl<sub>4</sub>, SnCl<sub>4</sub> (as previously known), PCl<sub>3</sub>, S<sub>2</sub>Cl<sub>2</sub>, SCl<sub>2</sub>, COCl<sub>2</sub>, POCl<sub>3</sub> and CrO<sub>2</sub>Cl<sub>2</sub> with sodium vapour.

<sup>9</sup> M. Polanyi and G. Schay, *Z. Physik*, 1928, 47, 814.

\* Existence doubtful.

The luminescences of the reactions of COCl<sub>2</sub> and PCl<sub>3</sub> with Na-vapour consist of the D-line; these cases, therefore, probably belong to type A. For COCl<sub>2</sub> the reaction might be

- (a)  $\text{Na} + \text{COCl}_2 = \text{NaCl} + \text{COCl}$ ,  
 (b)  $\text{Na} + \text{COCl} = \text{NaCl}^* + \text{CO}$ ,  
 (c)  $\text{NaCl}^* + \text{Na} = \text{NaCl} + \text{Na} + h\nu$ .

The heat of formation of COCl<sub>2</sub> from CO and 2Cl-atoms being 82 kCal., and the formation heat of two NaCl (vapour) from the atoms being 190 kCal., either reaction (a) or (b), and possibly even both, might possess a reaction heat of more than 48.5 kCal., which are necessary for the excitation of Na vapour. It seems probable, however, that such a reaction

heat is present only in reaction (b). No detailed suggestion can be given for the mechanism of the  $\text{PCl}_3$  luminescence.

The luminescence of  $\text{GeCl}_4$  is in every respect similar to that of  $\text{SnCl}_4$ , and might be accordingly accounted for by a mechanism of type B. Of the other chlorine compounds, only  $\text{SbCl}_3$  has a considerable intensity of chemiluminescence. Its spectral character appears to be a continuous band, extending from yellow to violet; very similar to the spectrum of the  $\text{SnCl}_4$  and  $\text{GeCl}_4$  luminescences. On this evidence it might be classified with these in group B. The luminescences of  $\text{S}_2\text{Cl}_2$  and  $\text{BCl}_3$  appear to be of similar character, but the light was too faint to permit a clear determination of the spectral character.

It is interesting to note that the reaction of  $\text{SiBr}_4$  is luminescent, although that of  $\text{SiCl}_4$  is not. There is a similar relation between  $\text{BBr}_3$  and  $\text{BCl}_3$ ; the luminescence of the bromine compound is considerably more intense than that of the chlorine compound. The rather incomplete spectral evidence indicates that the luminescence of  $\text{SiBr}_4$  and  $\text{BBr}_3$  belong to type B.

A very intense luminescence is obtained with  $\text{CrO}_2\text{Cl}_2$ , and a somewhat less bright one with  $\text{POCl}_3$ . Both luminescences are not of the colour of the D-line, and in consequence cannot belong to type A, but are probably of the type B.

There is a marked connection between the occurrence of the luminescences which we have classed under the type B, and the velocity of the reaction from which they arise. Of nine substances yielding a luminescence of this type, eight react instantaneously with sodium vapour.  $\text{BCl}_3$ , which forms an exception to this rule, gives only a very faint luminescence.

Not only do all luminescences emitting other light than that of the D-line (with one exception) come from instantaneous reactions, but also conversely, all the instantaneous reactions of polyhalides hitherto observed are accompanied by such luminescences.

A further series of luminescences appeared when oxygen was added to the reaction mixtures of  $\text{CS}_2$ ,  $\text{S}_2\text{Cl}_2$  and  $\text{SbCl}_3$  (Table III.). Sodium vapour and oxygen react with one another according to Haber and Sachsse,<sup>12</sup> through the primary formation of  $\text{NaO}_2$ , which is subsequently stabilized by collisions with the carrier gas; this reaction is accompanied by no visible luminescence. The reaction between sodium vapour and  $\text{CS}_2$  is, as was pointed out above, probably of a similar type to that of  $\text{Na} + \text{O}_2$ , and it likewise shows no trace of luminescence; it is only the mixture of  $\text{O}_2$ ,  $\text{CS}_2$  and Na which emits light. It is a bright radiation of the colour of the D-line.

The two luminescent reactions of sodium vapour with  $\text{S}_2\text{Cl}_2$  and  $\text{SbCl}_3$  are also profoundly modified by the addition of oxygen; a strong emission of the D-line arises in the presence of which the original luminescence can no more be observed; it could not be established whether it had actually vanished, or had only become invisible when outshone by light which arises on the addition of oxygen. Oxygen had no effect on the luminescences of  $\text{POCl}_3$  and  $\text{CrO}_2\text{Cl}_2$ .

The luminescences caused by the addition of oxygen resemble the luminescences classed above, under type C, which also require the presence of three reacting substances. We can offer no suggestion for this mechanism, and can note only that sulphur is present in each of the observed cases.

### Size of the Luminescent Zone.

The luminescent zone is of the same shape as the area filled with sodium vapour, by which the reaction zone (or "flame") is usually characterised (see Fig. 1). In the cases listed in Table IV. we have

TABLE IV.

Halogen Compound.	Diameter <i>D</i> of the Resonance Flame.	Diameter <i>D'</i> of the Luminescence Flame.	<i>D/D'</i> .
SnCl <sub>4</sub>	1.235	1.03	1.20
"	1.365	1.02	1.34
"	2.41	1.76	1.37
"	2.95	1.765	1.67
"	3.45	2.145	1.61
"	4.14	2.695	1.54
GeCl <sub>4</sub>	1.72	1.54	1.12
PCl <sub>3</sub>	2.99	~ 1.5	~ 2.0
"	3.66	~ 2.0	~ 1.8
"	3.99	~ 2.0	~ 2.0

measured the diameters both of the luminescent zone and of the sodium "flame"; the former appears to be always smaller than the latter. This proves that the light is stronger in the central parts of the "flame"; a fact easily to be explained by relating the intensity of the luminescence to reacting quantities per time and volume unit, which are higher in the interior parts of the flame than at its periphery.

### Summary.

1. The reaction velocities of a series of polyhalides (BCl<sub>3</sub>, BBr<sub>3</sub>, CCl<sub>4</sub>, SiCl<sub>4</sub>, SiBr<sub>4</sub>, GeCl<sub>4</sub>, SnCl<sub>4</sub>, TiCl<sub>4</sub>, PCl<sub>3</sub>, AsCl<sub>3</sub>, SCl<sub>2</sub>, S<sub>2</sub>Cl<sub>2</sub>, COCl<sub>2</sub>, POCl<sub>3</sub>, CrO<sub>2</sub>Cl<sub>2</sub>) reacting with sodium vapour have been determined by use of the "diffusion method."
2. Owing to the extreme rapidity of most of the reactions the rates of a few only could be quantitatively determined, while the order of magnitude and the sequence of reactivity were established for the rest. The polyhalides of the elements belonging to the middle groups of the periodic table show the highest inertia in reacting with Na-vapour.
3. In a homologous series the chemical inertia increases with the restoring force acting in the halogen linkage.
4. Na-vapour reacts with CS<sub>2</sub>-vapour; probably by a three-body collision.
5. Thirteen different new luminescences were observed arising from the reactions of Na-vapour with BCl<sub>3</sub>, BBr<sub>3</sub>, SiBr<sub>4</sub>, GeCl<sub>4</sub>, PCl<sub>3</sub>, SCl<sub>2</sub>, S<sub>2</sub>Cl<sub>2</sub>, COCl<sub>2</sub>, POCl<sub>3</sub>, CrO<sub>2</sub>Cl<sub>2</sub>, and from a mixture of Na-vapour and O<sub>2</sub> reacting with CS<sub>2</sub>, SCl<sub>2</sub>, and S<sub>2</sub>Cl<sub>2</sub>. A classification of these chemiluminescences according to principles previously established has been attempted.

The above experiments were carried out in the Kaiser Wilhelm Institut für Physikalische Chemie from January to August, 1933. The authors wish to recall in deep gratitude the memory of F. Haber who, during this period, was Director of the Institute.

# THE ABSORPTION OF GASES ON SODIUM CHLORIDE.

BY F. C. TOMPKINS.

*Received 8th January, 1936.*

Comparatively few adsorption measurements have been obtained with gases, at low pressures, on crystal surfaces. Langmuir<sup>1</sup> has shown that the adsorption of a number of gases on mica at 90° K., 155° K., and 183° K. can be represented by his theoretical equation. Bawn<sup>2</sup> has confirmed this with carbon monoxide and oxygen, but he could find no simple relation to express the results obtained with argon. He assumed that this gas covered more than one elementary surface, and that the equation must therefore be written:—

$$x = \frac{\sum K_1 c_1 c'_1 p}{1 + \sum c'_1 p},$$

where  $K_1$ ,  $K_2$ , etc., denote the relative areas of the various surfaces. The magnitude of these constants will largely determine the shape of the isotherm. Both he and Langmuir calculated that the thickness of the adsorbed layer was never greater than monomolecular, although the percentage of the surface covered at saturation varied considerably with different gases. The surface of mica is a complex distribution of atoms, and Langmuir suggests that the unsaturated carbon monoxide is adsorbed on all types of surfaces, whereas oxygen, for example, is only attached to the metallic atoms, and hence will have a low saturation value.

Durau<sup>3</sup> has studied the adsorption of various gases on sodium chloride at higher pressures, and optical examinations of the adsorbed layer of methanol on a single crystal of this salt have been made by Silvermann<sup>4</sup> and Frazer.<sup>5</sup> They find the layer to be monomolecular, but Whipp;<sup>6</sup> however, in an attempt to explain the abnormal form of the isotherm in the adsorption of iodine by crystals of potassium chloride, has postulated the formation of a second layer at higher pressures.

There are, unfortunately, few data available to verify the calculations of Lennard-Jones<sup>7</sup> concerning the nature and magnitude of the adsorptive forces operative at the surface of crystals. A preliminary survey of the adsorption of ten gases by sodium chloride crystals at 90° K. and 183° K., at low pressures has therefore been made in order (a) to test the possibility of lateral diffusion of adsorbed molecules; (b) to measure their heats of adsorption at low temperatures; and (c) to correlate the adsorbability of the gases with their physical properties.

## Experimental.

### Preparation of Materials.

**Sodium Chloride.**—Very small and fairly uniform crystals were obtained by passing a rapid stream of pure hydrochloric acid gas into a saturated solution of A.R. sodium chloride. After two precipitations, the salt was filtered through a ground glass plate, and dried in a vacuum dessicator over caustic potash and phosphorus pentoxide, for a month. The average dimensions of the crystals (assumed to be cubic) were measured by a high-power microscope. The mass of the salt was 65.4 grams, and its total surface area was estimated to be approximately 45,000 sq. cms.

**Argon.**—Impure argon and oxygen were sparked between platinum electrodes for six hours. Oxides of nitrogen were absorbed by 40 per cent. caustic potash and excess oxygen was removed by combining with freshly reduced copper at 350° C., and the argon finally dried over phosphorus pentoxide.

**Carbon Monoxide.**—100 per cent. formic acid was added to concentrated sulphuric acid, and the gas purified by passing over caustic potash and through a liquid-air trap, and dried by phosphorus pentoxide.

**Methane** was prepared for this work by Dr. M. W. Travers from dilute hydrochloric acid and aluminium carbide and purified by repeated fractional distillations.

**Oxygen.**—Pure potassium permanganate was heated and the gas passed over solid caustic potash and phosphorus pentoxide.

**Nitrogen.**—This gas was supplied by Dr. Travers, and was obtained from ammonia, which had been purified by fractional distillation, by oxidation, using a mixture of copper oxide and copper at 400° C. The latter prevents the formation of any oxides of nitrogen. Water vapour was removed by condensation in a liquid-air trap.

**Nitric Oxide.**—50 per cent. sulphuric acid was added to a mixture of two parts by weight of potassium nitrate, and one part of potassium iodide.<sup>8</sup> The gas was passed over caustic potash and phosphorus pentoxide and condensed into a liquid-air trap. The nitric oxide was kept in the liquid state while a further supply of the gas was passed through it, in order to remove any nitrous oxide present.<sup>9</sup> The product was then repeatedly distilled and fractionated. The last traces of nitrogen and nitrous oxide were removed by twice subliming the nitric oxide under a pressure of 17 mm., and finally condensing it at 50 mm. pressure. Analysis was performed by mixing with pure oxygen and absorbing the nitrogen peroxide by monoethylamine.<sup>10</sup>

**Nitrous Oxide.**—Cooled concentrated hydroxylamine hydrochloride was added to sodium nitrite solution. The gas was passed through caustic potash solution, and concentrated sulphuric, and dried over phosphorus pentoxide. The product was fractionated repeatedly, and its purity tested by measuring its vapour pressure at -78.2° C.

**Carbon Dioxide.**—This was obtained from sodium bicarbonate and dried over phosphorus pentoxide.

**Cyanogen.**—Pure mercuric cyanide was heated and the cyanogen condensed and fractionated.

**Ethylene.**—A mixture of concentrated sulphuric acid and ethyl alcohol was heated to 160° C. The gas was passed through caustic potash solution cooled in a freezing mixture and then fractionated.

### Apparatus.

The apparatus, which is shown diagrammatically in Fig. 1, consisted of a calibrated gas burette, C, two McLeod gauges, M<sub>1</sub> and M<sub>2</sub>, together

<sup>8</sup> Winkler, *Ber.*, 1901, 34, 1408.

<sup>9</sup> Gray, *J.C.S.*, 1905, 87, 1601.

<sup>10</sup> Koehler and Marqueryrol, *Bull. Soc.*, 1913, 13, 69.

with the system A, and a duplicate blank one, B. These latter contained adsorption vessels,  $V_1$  and  $V_2$ , liquid-air traps,  $T_1$  and  $T_2$ , and mercury seals,  $bd$  and  $cg$ , and were such that their total volume and total glass surface were the same. Pointers,  $a, b, c, d, e$  and  $f$ , etc., were fused into the seals in order that the mercury levels could be adjusted to definite positions. The volumes of the traps and the vessels were determined before being incorporated in the apparatus. All glass tubing was of 1 cm. internal diameter. The apparatus could be exhausted by a glass-mercury diffusion pump, backed by a Hyvac oil pump, to a pressure of less than  $1 \times 10^{-6}$  cm. mercury. The two gauges had a range from  $1 \times 10^{-4}$  to  $1 \times 10^{-1}$  cm., and were accurately calibrated. The gas burette was used in the determination of the volumes of the various systems and also for the admission of gas during adsorption measurements.

FIG. 1

### Calibrations.

Hydrogen was used throughout, since it is not appreciably adsorbed on glass at  $90^\circ \text{K.}$  (<sup>1</sup> and <sup>2</sup>). A known quantity was admitted into the various systems from the gas burette, and the volumes calculated by means of the gas laws. Extensive calibrations were made in order to correct for the thermomolecular flow which occurs at temperature junctions at low pressures. These are recorded elsewhere.<sup>11</sup>

### Procedure.

Outgassing of the surface was effected by evacuating the adsorbent at  $350^\circ \text{C.}$ , for sixteen hours, during which time the trap  $T_1$  was immersed in a bath of solid carbon dioxide and alcohol for the first fourteen hours, and in liquid air for the remaining two. The salt was cooled for two hours, after which period a small pressure of hydrogen was admitted and the adsorption vessel immersed in liquid air for an hour. The hydrogen was then pumped out. This procedure accelerated the establishment of thermal equilibrium, since otherwise the chief mode of heat distribution in a hard vacuum is by conduction through the adsorbent itself, which has a low

<sup>11</sup> Tompkins and Wheeler, *Trans. Faraday Soc.*, 1933, **29**, 1248.

thermal conductivity. The cooling process had no effect on the magnitude of the adsorption, but without it, spurious rate curves had been obtained with the first admission of the adsorbate.

During adsorption measurements, the system B, was cut off by the U-seal, *cg*, and after outgassing and cooling, the pumps and the vessel,  $V_1$ , were isolated by the seals, *a* and *b*. Gas was admitted from the gas burette and the seals levelled to *e* and *f*. From the pressure recorded in the McLeod gauge, the amount introduced was calculated. This was expanded into the system, A, and the equilibrium pressure recorded. This is not the pressure in the gauge, since corrections have to be applied for thermo-molecular flow. From the calibration curves,<sup>11</sup> the actual pressure in the vessel,  $V_1$ , can be easily found. The amount of gas remaining in the gas phase—again with the appropriate corrections—was thus known, and the difference of this and the quantity initially introduced, measured the adsorption on the salt and on the glass. The adsorbent was again isolated,

FIG. 2.

the pressure measured, and a further amount of gas introduced. The increase of pressure gave the magnitude of the additional quantity, and hence the total amount of gas admitted. This was expanded into the system, A, and the amount adsorbed at this higher equilibrium pressure calculated as before. The process was repeated until a pressure of  $4 \times 10^{-3}$  cm. was reached. The series was then discontinued, since the accuracy decreases with each addition of gas. The amount adsorbed, however, at any pressure was quite independent of the number of increments by which the pressure was built up. Similar measurements in the system, B, were made under identical conditions, in order to measure the adsorption on the glass surface alone. This was so small that it has been neglected.

## Results.

### Adsorption of Argon.

The amount of argon adsorbed at any pressure at  $-183^\circ \text{C}$ . depends largely upon the conditions of outgassing. Typical isotherms (Fig. 2,

$A_1$  and  $A_2$ ) show that there is a large, but variable adsorption at low pressures, but that Henry's law is obeyed at higher concentrations, and that the plots are parallel to one another. It is suggested that the first few milli-c.c. are adsorbed on high potential areas of the surface such as, at re-entrant angles, or linearly along the mouths of Smekal cracks. Outgassing, therefore, affects the potential and extent of such areas, but the main surface is unaltered.

After a carbon monoxide isotherm had been determined, the adsorption of argon was reversible and reproducible, but the amounts were smaller in magnitude than in any previous determination. The strongly unsaturated carbon monoxide, which covers nearly all the surface, had probably partially poisoned the active centres, and outgassing at  $350^\circ\text{C}$ . was ineffective in removing it. Even when the temperature was raised to  $500^\circ\text{C}$ ., the initial portion of the argon isotherm was practically unchanged, thus showing that these active areas had not been affected. The car-

FIG. 3.

bon monoxide isotherm, however, was lowered. Sintering had probably occurred, causing the coalescence of micro-crystals on the main surface, thus reducing the effective area of the adsorbent. Argon isotherms determined subsequent to this, were also lower than those previously obtained. This was probably due to an increase in the poisoning action of carbon monoxide. Methane isotherms also showed a decrease, similar to that of carbon monoxide. The adsorbent was then treated with oxygen at  $500^\circ\text{C}$ . in order to remove the carbon monoxide chemically as carbon dioxide, but this caused a further decrease in the adsorption of argon. Treatment with hydrogen and also with carbon monoxide at  $350^\circ\text{C}$ ., had no effect. Chemisorption, or surface chemical reaction with the formation of a small amount of sodium oxide<sup>13</sup> had probably occurred, since the introduction of hydrochloric acid gas restored the surface to its original condition after a further outgassing. Although the surface was probably

<sup>13</sup> Lange and Dürr, *Z. Elektrochemie*, 1926, 32, 85.

slightly contaminated with carbon monoxide, no further attempts were made to clean it. Argon isotherms, which were periodically determined, showed however that it possessed constant adsorptive capacity and remained in a steady condition throughout all subsequent measurements.

### Adsorption of Argon, Methane, Oxygen, Nitrogen, etc.

Isotherms obtained with these gases on the above surface at  $-183^{\circ}\text{C}$ . are collected together in Figs. 2 and 3. The adsorption of all of them at  $-78.2^{\circ}\text{C}$ . was too small to be measured. Fig. 4 gives isotherms obtained with cyanogen, nitrous oxide, carbon dioxide and ethylene at this latter temperature and on the same surface.

A few measurements with argon, methane and carbon monoxide were made at  $-192^{\circ}\text{C}$ . (liquid nitrogen), in order to obtain values for the heat

FIG. 4.

of adsorption, by comparing the amounts adsorbed at  $-192^{\circ}\text{C}$ ., and at  $-183^{\circ}\text{C}$ . The argon isotherm at  $-192^{\circ}\text{C}$ . differed from that at the higher temperature only in the magnitude of the initial process, and the plots were parallel at higher pressures. Consequently, there is no change in the amount adsorbed with temperature in this region and the calculated heat of adsorption is zero. A value of 300 Cals. was obtained with methane at higher concentrations. Bawn (*loc. cit.*) gives 334 Cals. for the heat of adsorption of this gas on mica at low temperatures. In the present investigation a heat of 350 Cals. was found for carbon monoxide, and this remained constant throughout the pressure range studied. In his theoretical calculations, Lennard-Jones<sup>13</sup> has given 3000 Cals. as the heat of adsorption of argon on sodium chloride, but with the later data of London,<sup>14</sup> this has been reduced<sup>15</sup> to 1000-1500 Cals. Wilkins<sup>16</sup> finds that the

<sup>13</sup> London, *Z. physik. Chem.*, 1931, 11 B, 222.

<sup>14</sup> Lennard-Jones, *Trans. Faraday Soc.*, 1932, 28, 333.

<sup>15</sup> Wilkins, *ibid.*, 1932, 28, 438.

latter figure is in better agreement with his experimental results. Lenel,<sup>16</sup> however, supports the former, both theoretically and experimentally. He has, however, assumed that the Langmuir equation is applicable, and, moreover, no correction was made for thermo-molecular flow and the adsorption was measured at low concentrations, where higher values are to be expected, since high potential areas are covered initially.

It is perhaps a coincidence, rather than significant, that the same type of isotherm is obtained with gases which are isosteres. The isotherms of carbon monoxide and nitrogen, and of carbon dioxide and nitrous oxide follow the Langmuir equation closely; those of oxygen and ethylene obey the Freundlich expression, and those of argon and methane show similar characteristics.

### Discussion.

A quantitative treatment of the adsorptive forces, which are operative at the surface of heteropolar crystals, has been given by Lennard-Jones.<sup>14</sup> They comprise (a) van der Waals, or dispersive forces, which according to London,<sup>15</sup> are approximately proportional to the square root of the van der Waals constant,  $a$ , and which represent general forces of adhesion, analogous to gravitation; (b) electrostatic forces, which become important when the adsorbent is a metal, or is composed of ions and the adsorbate is polar; (c) polarisation forces, which are produced by the surface field inducing a non-uniform charge distribution in the adsorbed molecule; and lastly, (d) a much smaller force, which has not, as yet, been evaluated and which represents the reaction of the adsorbent to the charges on its surface. It is shown by London (*loc. cit.*) that the adsorption on amorphous substances is largely controlled by the van der Waals forces, but the electrostatic forces are the more important in the adsorption of gases on metals (Lennard-Jones<sup>14</sup>). The calculations of Lennard-Jones emphasise the small contribution of the electrostatic forces in the adsorption on crystal surfaces, and therefore the adsorbability of gases on sodium chloride should follow the magnitude of their respective van der Waals  $a$  constants, and thus be comparable to that on homopolar adsorbents.

Table I. gives the adsorption of nitric oxide, carbon monoxide, methane, nitrogen, argon and oxygen at  $-183^{\circ}\text{C}$ ., and of cyanogen, carbon, dioxide, nitrous oxide and ethylene at  $-78.2^{\circ}\text{C}$ ., in c.c. at  $0^{\circ}\text{C}$ . and 760 mm. pressure, at pressures of 1 and  $2 \times 10^{-2}$  cm. mercury, together with the comparative data of Bawn and Langmuir for the adsorption of gases on mica at  $-183^{\circ}\text{C}$ .. These latter figures represent the percentage saturation, *i.e.* the percentage of the surface covered at saturation. The amounts of methane, carbon monoxide and of argon adsorbed on the glass in the present series at  $-183^{\circ}\text{C}$ ., at  $1 \times 10^{-2}$  cm. pressure are also given. The remaining columns give the values of the polarisability of the gases, according to London,<sup>15</sup> the van der Waals  $a$  constant, and the electric moment of the dipole molecules in the appropriate units.

With all gases, the amounts adsorbed are small and since there is always a rapid attainment of equilibrium, the process entirely reversible, and the heats of adsorption are low, the adsorption must be van der Waals in character. There is however no simple relationship between the van der Waals constant and the adsorbability, such as that indicated by London and suggested by the calculations of Lennard-Jones. Attention is drawn to the extremely large adsorption of the two polar gases,

<sup>16</sup> Lenel, *Z. physik. Chem.*, 1933, **23 B**, 379.

nitric oxide and carbon monoxide, at  $-183^\circ \text{C}$ ., although the value of their  $a$  constants are smaller than that of methane, which is not strongly adsorbed. This peculiarity seems to be confined to heteropolar surfaces, since the results of Bawn on mica, and of Durau<sup>3</sup> on sodium chloride at  $0^\circ \text{C}$ ., show that carbon monoxide is more highly adsorbed than methane, whereas the reverse is found on glass, and on charcoal.<sup>17</sup> It must, therefore, be concluded that it is the electrical forces occurring at the heteropolar surface, together with the dipole character of the adsorbate, which largely decides the amount of gas adsorbed. The dipole moment is again the important factor in the adsorption of gases at  $-78.2^\circ \text{C}$ ., with the exception of carbon dioxide which is discussed later. Cyanogen, for example, has the largest moment, and is most highly adsorbed, whereas the adsorption of the non-polar, unsaturated ethylene is exceedingly small. The dipoles carried by polar molecules, however, will contribute only in a minor degree to the value of the van der Waals constant, owing to the random movement of the molecules in the gas phase. Since the magnitude of this constant determines the adsorbability of a gas on a homopolar adsorbent, the possession of a dipole moment will cause little increase in the amount of gas adsorbed. With a heteropolar surface, dipoles are attached to it in an oriented manner, and thus considerably increase the electrostatic force, and so cause a large increase in the adsorption.

Nevertheless, the theoretical curves giving the variation of van der Waals and electrostatic forces as functions of the distance of the adsorbed molecule from the surface of a crystal,<sup>7</sup> show that the contribution of the latter to the total adsorption potential, at the normal equilibrium distance of 3 to 4 Å., is much less than that of the van der Waals forces. The electrical forces are short ranged in effect, but, since they increase with extreme rapidity, they become the larger at smaller distances. The great effect produced by the presence of small dipoles on the adsorbability of the gases on sodium chloride, suggests that a closer approach

<sup>17</sup> Arrhenius, *Medd. Nobelinst.*, 1911, 2, 7. (As to adsorption on glass, see Table I, above.)

of the molecules to the surface occurs. This is possible from spatial considerations, but it would necessitate a large increase in the heat of adsorption, unless there was a correspondingly large increase in the electrostatic repulsive forces. Herzfeld<sup>18</sup> has shown that these would contribute a large negative part to the total heat and would also fix the equilibrium position. They are certainly important in the adsorption of gases on metals, and in such systems the electrostatic forces do account for the greater part of the adsorption potential, as, for example, in the adsorption of nitrogen on copper.<sup>14</sup> A metal, however, is a perfectly polarisable system; nevertheless, there must be a similarity in the surface fields of metals and ionic crystals, since a metal is built up of a lattice of positive ions with free electrons approximately uniformly distributed between them. This similarity is emphasised in the above results, where it is seen that the electrostatic forces control to a large degree the magnitude of the adsorption. It must, therefore, be concluded that, either the approach of the adsorbed molecule to the surface is closer than has hitherto been assumed and that there are large electrostatic repulsive forces operating, or, that a crystal acts as a pseudo-polarisable system, and that the method of electrical images is applicable in the estimation of the electrical forces to the adsorption potential. This latter assumption has been used in a general manner by Magnus in his electrical theory of adsorption.<sup>19</sup>

In the adsorption of non-polar gases, the polarisability of the adsorbate is the most important property, as has been deduced by London in his dispersion theory.<sup>12</sup> Methane (Table I.) is the most highly adsorbed, and is the most easily polarisable, whereas oxygen and argon with low polarisabilities are adsorbed approximately to the same small extent. No simple quantitative relation of adsorbability and polarisability is expected, since the equilibrium distances of the adsorbed molecule vary with the gases, and also because the forces operating are not simply due to a mutual polarisation of like molecules, but to forces acting between molecules of the adsorbate and two systems of oppositely charged ions on the surface.

The adsorption of the non-polar carbon dioxide is "abnormal" in so far as the amount adsorbed is larger than that expected from its polarisability. It is probable that this molecule, being linear in structure, becomes attached by the oxygen atoms at two points when adsorbed, and lies flat on the surface. The surface field of the crystal induces an electric charge in one of these, and this is transmitted through the molecule with the result that a charge of opposite sign is produced in the other oxygen atom. Since the distance between the sodium and chlorine ions in the crystal lattice approximates to that between these two atoms, each of these latter will be in the vicinity of an ion carrying a charge, which is opposite in sign to that of the neighbouring oxygen atom. The forces which are holding the molecule to the surface will therefore be considerably increased, and the rate of evaporation retarded. This phenomenon should occur whenever the distance between two like atoms of a linear non-polar adsorbate molecule is about the same as that between two different ions of a crystal surface lattice. Nitrous oxide, on the contrary, is polar, and the molecule does not lie flat on the surface, since oriented adsorption occurs.

<sup>18</sup> Herzfeld, *J.A.C.S.*, 1929, 51, 2608.

<sup>19</sup> Magnus, *Trans. Faraday Soc.*, 1932, 28, 386, etc.

The sharp initial rise in the argon and methane isotherms has been identified with adsorption on active centres. Since the calculated heats of adsorption in the higher pressure range are either low, or zero, it is probable that all of the adsorption occurs on active patches and the straight part of the isotherm at higher pressures merely represents the complete saturation of such patches. The initial adsorption has associated with it a heat of adsorption, since the amount adsorbed in this region varies with the temperature; the linear adsorption, however, does not change with the temperature with argon, and only slightly with methane, as is expected if the additional gas only saturates these active areas. The adsorption of these gases will take place in the neighbourhood of the smaller sodium ion, where the external field is a maximum. Consequently, repulsive forces will act between similar dipoles which are induced in adjacent adsorbed molecules, and these forces will mainly determine the shape of the isotherm. Fuchs<sup>20</sup> has shown that isotherms of the same type as found in this work with argon and methane are obtained when such repulsive forces are assumed in a hypothetical one-dimensional adsorption. The presence of small high potential areas is expected to have little effect on the carbon monoxide isotherm, since most of the adsorption is on the main crystal surface, which must be approximately equipotential. This is confirmed by the constant heat of adsorption and the applicability of the Langmuir equation throughout the range of measurements.

The shape of the nitric oxide isotherm indicates the presence of large attractive forces between adsorbed molecules,<sup>20</sup> and is comparable to that found by Polanyi and Welke<sup>21</sup> with sulphur dioxide on charcoal. Nitric oxide covers about 90 per cent. of the measured surface at saturation so that the adsorption must occur over both ions of the crystals. Consequently, induced dipoles of opposite sign are adjacent on the surface and this orientation produces a large attraction between the adsorbed molecules, which will be further increased, particularly at low temperatures, by the presence of the strong electric field at the surface. Since there is evidence, for example, from specific heat<sup>22</sup> and vapour pressure measurement,<sup>23</sup> and from the high Trouton constant and the abnormal density at the boiling-point,<sup>23</sup> of the association of nitric oxide in the liquid and gas phase at low temperatures, and since the attraction is much larger when the gas is adsorbed, molecular aggregates are probably formed in the surface layer. At low pressures, Henry's Law is obeyed (Fig. 3). This linear portion represents the adsorption of simple NO molecules, but in the region where the curve rises abruptly, association begins, and as the curve bends over in the normal manner towards saturation, only doublet molecules are adsorbed. It is seen, for example, that the Henry region ends when 0.35 c.c. of gas has been adsorbed, and that the bending over commences when twice this amount has been taken up by the adsorbent.

The adsorption of all gases at  $-192^{\circ}\text{C.}$  and  $-183^{\circ}\text{C.}$  was almost instantaneous, but at  $-78.2^{\circ}\text{C.}$ , a very slow secondary process was found with the highly adsorbed gases. The critical temperature of lateral diffusion must therefore be within these two limits. This is in accord with the value ( $150^{\circ}\text{K.}$ ) found theoretically by Lennard-Jones.<sup>14</sup>

### Summary.

1. The adsorption of ten gases on sodium chloride crystals at low temperatures and pressures has been investigated.
2. The surface is very sensitive to impurities and to variations in the conditions of outgassing.
3. Dipole gases are highly adsorbed according to the value of their electric moment; there is a parallelism between the adsorbability of non-polar gases and their polarisability.
4. The shape of the isotherms are qualitatively explained by assuming that there are forces operating between adsorbed molecules. Association of nitric oxide occurs in the surface layer, and carbon dioxide lies flat on the surface when adsorbed.
5. The heats of adsorption of argon and methane and carbon monoxide in the temperature range  $-183^{\circ}\text{C.}$  —  $-192^{\circ}\text{C.}$  are much smaller than anticipated from theoretical considerations.
6. There is no lateral diffusion of adsorbed molecules at  $-192^{\circ}\text{C.}$  or at  $-183^{\circ}\text{C.}$ , but a slow secondary absorption is found at  $-78.2^{\circ}\text{C.}$

The author wishes to express his thanks to Professor W. E. Garner and to Professor A. J. Allmand for constant interest and advice during the course of the investigation; and also to the Dept. of Scientific and Industrial Research for a maintenance grant and to the Imperial Chemistry Industries for a grant for the purchase of apparatus.

## NOTE ON THE SURFACE TENSION OF SOAP SOLUTIONS.

BY N. K. ADAM.

*Received 11th February, 1936.*

Most of the recorded observations on the surface tension of soap solutions are on carefully neutralised solutions. The results of different workers, and even of the same worker under slightly different conditions, are not very concordant, and Lottermoser and his co-workers<sup>1</sup> have found that carbon dioxide in the air causes a slow decrease in tension, in some solutions, and that the nature and treatment of the glass vessels containing the solutions affects the tension. He ascribes this to hydrolysis of the soap, and concludes that it is very difficult to obtain reproducible results for the surface tension of soap solutions. A change in the small amount of hydrolysis in the interior may be expected to produce a very considerable change in the equilibrium between interior and surface, if the free acid, or acid soap, produced by hydrolysis is much more strongly adsorbed than the neutral soap. Since the  $\text{COOH}$

<sup>1</sup> *Trans. Faraday Soc.*, 1935, **31**, 200; *Kolloid-Z.*, 1935, **73**, 155, 270; *Kolloid-Beihfte*, 1935, **51**, 73.

group has a much smaller attraction for water than  $\text{COONa}$ , it is to be expected that free acid will be more strongly adsorbed than neutral soap. It has, moreover, been shown, by analysis of the foam on soap solutions, by Perrin,<sup>2</sup> Miss Laing,<sup>3</sup> and Laing, McBain and Harrison,<sup>4</sup> that the soap present in the surface layer of neutral soap solutions contains a large excess of acid; that obtained from a slightly alkaline solution is, however, neutral.

The effect of the addition of small amounts of alkali to soap solutions, on the surface tension, can also be explained if the free acid, or acid soap, produced by hydrolysis, is much more strongly adsorbed than the neutral soap. Harkins and Clark,<sup>5</sup> Ekwall,<sup>6</sup> and Powney<sup>7</sup> found that the tension of "neutral" soaps is of the order 20-25 dynes per cm., this tension remaining practically unchanged (with a soap of twelve or more carbon atoms) as the concentration increased from  $N/500$  upwards. Addition of a very small amount of alkali increases the surface tension very rapidly, to a maximum which is about 62 dynes per centimetre for a  $N/500$  potassium laurate solution, but decreases as the solution becomes more concentrated. Rather more alkali must be added to reach this maximum of tension, the stronger the solution of soap, but the amounts required are quite small. If alkali is added in quantities much greater than that necessary to reach the maximum of tension, the tension decreases slowly and almost linearly with increasing alkali concentration; but it always remains far above the tension of a neutral soap solution.

Qualitatively, the very low tension found with the "neutral" solutions is that appropriate to a solution with a surface layer practically saturated with adsorbed molecules; as the tension is very much raised on adding a little alkali, which suppresses hydrolysis, the adsorbed layer is probably mainly acid or acid soap. The maxima of tension probably occur where the alkali is just sufficient to suppress hydrolysis practically completely; more alkali has to be added to the stronger solutions to reach these maxima because more is needed to suppress the hydrolysis. The equilibrium between interior and surface now concerns neutral soap molecules only, and the surface is not nearly saturated at  $N/500$  nor is it completely saturated even at  $N/50$ .

A close approximation to the true surface tension-concentration curve for a solution containing no capillary active molecules except neutral soap is probably given by plotting the maxima of curves such as those given by Powney\* against the concentration of soap (potassium laurate). From the surface tension-concentration data the state of the adsorbed film may be deduced by Gibbs' adsorption equation. In the table, the molar concentration  $m$ , the activity coefficient  $f$ , given by Randall, McBain and White<sup>8</sup> (interpolated as for a dilute uni-univalent electrolyte), the depression of surface tension  $F$ , given by Powney, the adsorption  $\Gamma$  calculated by Gibbs' equation from the slopes of the smoothed curve relating  $F$  to  $\log fm$ , and the area per molecule in the adsorbed film, are given.

## ADSORPTION OF NEUTRAL POTASSIUM LAURATE MOLECULES.

Concentration (Moles per Litre), <i>m</i> .	Activity Coefficient, <i>f</i> .	Depression of Surface Tension, <i>F</i> .	Absorption: Molecules per Sq. Cm., <i>Γ</i> .	Area per Molecule, Sq. Å., <i>A</i> .
0.0021	0.95	11.1	$2.59 \times 10^{14}$	38.6
0.0042	0.93	19.8	2.92 ..	34.3
0.0084	0.90	25.9	3.13 ..	31.9
0.0126	0.88	30.7	3.46 ..	28.9
0.021	0.85	38.2	3.78 ..	26.5

The relation between  $F$  and  $A$  is that of a typical "gaseous" film under rather high surface pressure. The surface is not completely saturated even at the highest of the concentrations here measured.

The slow decrease in surface tension observed when much larger amounts of alkali are added is perhaps due to incipient salting out of the soap; it would be interesting to see whether neutral salts produce the same effect as the alkali added in excess of the amount required to reach the maximum of tension.

The fact that the tension in neutral solutions at concentrations as low as  $N/500$  has reached the minimum of 22 dynes per centimetre indicates that the acid, or acid soap, is exceedingly strongly adsorbed.

Assuming the usual formula for the fraction hydrolysed,  $\sqrt{\frac{k_w}{mk_a}}$ , and taking the dissociation constant  $k_a$  of lauric acid as  $1.4 \times 10^{-5}$ , the concentration of undissociated lauric acid in the interior of the  $N/500$  soap should be about  $1.2 \times 10^{-6} N$ . A solution of lauric acid in water containing this concentration of undissociated acid would have a total concentration of  $5.3 \times 10^{-6} N$ , if the above dissociation constant is assumed.

Frumkin's data<sup>9</sup> on the surface tension of solutions of lauric acid give, at 18°, a depression of about 22.5 dynes per centimetre in water for this concentration. This is smaller than the change in surface tension (about 40 dynes) caused by suppressing hydrolysis in  $N/500$  potassium laurate; but Frumkin also says that very much greater depressions of tension were obtained if the lauric acid solutions had their surfaces contracted just before taking the measurements; moreover his method of measurement, withdrawing a vertical thin plate from the surface, would be likely to extend the surface, reducing the surface concentration of the adsorbed molecules, which would be but slowly made up in these very dilute solutions; there is a probability that his results for the tension are too high and for the depression of tension too low. At any rate, it can be said that the amount of acid produced by hydrolysis in a "neutral" soap solution would be expected to produce a very large lowering of surface tension.

The very great magnification of hydrolysis in the surface layer, due to the much greater surface activity of the acid over that of the soap, renders experiments on the surface properties of "neutral" soap solutions liable to unexpected errors. It would therefore appear desirable, in measuring any surface properties of soap solutions, to add sufficient alkali to suppress hydrolysis, or at any rate to take very great care that the  $p_H$  of the solution is exactly controlled.

<sup>9</sup> *Z. physikal. Chem.*, 1925, 116, 482.

### Summary.

The effects of slight traces of alkali in raising the surface tension of soap solutions are explained as due to suppression of hydrolysis, which is very much magnified in the surface layers, since the surface activity of the acid, or acid soap, is very much greater than that of neutral soap. The adsorption of neutral potassium laurate is calculated from published data, and the adsorbed film is found to be gaseous, of the usual type.

I am indebted to Mr. G. S. Hartley for helpful discussion.

## THE KINETICS OF POLYMERISATION PROCESSES. PART II.

BY GEOFFREY GEE.

*Received 3rd February, 1936.*

In an earlier paper<sup>1</sup> the kinetics of polymerisation processes was discussed, and reasons were advanced for the view that in many cases a steric factor is the important factor in controlling the size of the final polymer. A similar view has been put forward by Bawn,<sup>2</sup> while Dostal and Mark<sup>3</sup> do not consider that the steric factor can be much affected by chain length. It is perhaps necessary to point out here that the definition of "steric factor" employed in Part I. leads to an unusual interpretation of the reaction velocity constants. The equations are there derived in terms of the number of molecules  $n_r$  of the polymer  $M_r$ , reckoned in terms of the monomer, so that  $n_r$  is proportional to the mass of  $M_r$  and the velocity constant  $k_r$  (for the addition of  $M$  to  $M_r$ ) is thus defined in terms of the masses of the reactants. To transform from this system to the more conventional one which employs molecular concentration it is clearly necessary to introduce a factor  $1/r$ . The net result of carrying out this process is to multiply the steric factor by  $r$ , so that the equations given in Part I. for a process with a steric factor  $1/r$  are strictly comparable with those derived by Dostal and Mark.<sup>3</sup> By the introduction of a function  $Z$  termed the *Eigenzeit* these authors were able to give a rigid integration of the differential equations set up for the concentrations of the various polymers, and to obtain expression for these concentrations in terms of  $Z$ . As  $Z$  is not directly measurable their results are not immediately applicable to experiment and it therefore appears desirable to give here a few notes on the relationship between the results of the two methods of analysis before proceeding to discuss other polymerisation mechanisms.

<sup>1</sup> Gee and Rideal, *Trans. Faraday Soc.* 1935, **31**, 969.

<sup>2</sup> Bawn, *ibid.*, 1936, **32**, 178.

<sup>3</sup> Dostal and Mark. (a) *Z physik. Chem.* 1935, **29B**, 299; (b) *Trans. Faraday Soc.*, 1936, **32**, 54.

In this paper we shall modify slightly the nomenclature of Part I. since it will be necessary to distinguish between active and inactive polymers. We shall therefore denote the various inactive molecular species by  $M_1, M_2, M_3, \dots, M_r, \dots$ ; the corresponding active bodies by  $M_1', M_2', M_3', \dots, M_r', \dots$ ; and their concentrations (in terms of monomer) by  $n_1, n_2, \dots, n_r, \dots$ ;  $n_1', n_2', \dots, n_r', \dots$  respectively. If  $n_0, N$  are respectively the numbers of molecules present initially and at time  $t$ , then obviously

$$n_0 = (n_1 + n_1') + (n_2 + n_2') + \dots + (n_r + n_r') + \dots \quad (1)$$

$$N = (n_1 + n_1') + \frac{1}{2}(n_2 + n_2') + \dots + \frac{1}{r}(n_r + n_r') + \dots \quad (2)$$

In the case so far discussed the only inactive body present is  $M_1$ , so that  $n_2 = n_3 = \dots = n_r = 0$ , and the reaction is represented by:

The velocity constant of the activation reaction is  $\alpha k n_0$  as before; the other reactions all have a velocity constant  $K$  (in terms of concentrations), so that we have

$$\left. \begin{array}{l} -\frac{dn_1}{dt} = K n_1 \left( \alpha n_0 + n_1' + \frac{1}{2} n_2' + \dots + \frac{1}{r} n_r' + \dots \right) \\ \frac{dn_1'}{dt} = K n_1 (\alpha n_0 - n_1') \\ \vdots \\ \frac{dn_r'}{dt} = r K n_1 \left( \frac{n_{r-1}'}{r-1} - \frac{n_r'}{r} \right) \end{array} \right\} \quad (4)$$

We now introduce the function  $Z$ , defined by

$$Z = K \int_0^t n_1 dt \quad (5)$$

This differs from Dostal and Mark's definition by the factor  $K$ , and thus obviates the dimensional difficulties of their paper by making it clear that  $Z$  is a pure number. In a similar way, Dostal and Marks constant " $a$ " is replaced here by  $\alpha n_0$  where  $\alpha$  is unambiguously a fraction. It can then be shown\* that

$$\frac{1}{r} n_r' = \alpha n_0 e^{-Z} \sum_{r=1}^{\infty} \frac{Z^r}{r!} \quad (6)$$

$$n_1 = n_0 (1 - \alpha Z - \frac{1}{2} \alpha Z^2) \quad (7)$$

$$N = n_0 (1 - \frac{1}{2} \alpha Z^2) \quad (8)$$

\* The derivation follows the method of Dostal and Mark; the slight change in equation (6) arises because these authors have made the unnecessary approximation of putting  $\frac{dn_1'}{dt} = 0$ .

It was shown in Part I. that the mean chain length  $\nu$  of the polymerised fraction is given by :

$$\nu = \frac{n_0 - n_1}{N - n_1} \quad (9)$$

and combining with (7) and (8) we find

$$\nu = 1 + \frac{1}{2}Z \quad (10)$$

so that  $Z$  is approximately equal to twice the mean chain length of the polymerised fraction.

Combining these results with those of Part I. it is easily shown that the reaction velocity is given by :

$$-\frac{dN}{dt} = 2\alpha K n_0 \left[ N \left\{ 1 + \sqrt{\frac{n_0 - N}{2\alpha n_0}} \right\} - n_0 \right] \quad (11)$$

or in terms of the fraction polymerised  $x \left( = 1 - \frac{n_1}{n_0} \right)$

$$\frac{dx}{dt} = \alpha K n_0 (1 - x) \sqrt{1 + \frac{2x}{\alpha}} \quad (12)$$

while the mean chain length  $\nu$  is found to be

$$\nu = 1 + \sqrt{\frac{n_0 - N}{2\alpha n_0}} \quad (13)$$

By differentiation of (11) it is easily shown that the condition for the velocity to be a maximum is

$$\left( \frac{N}{n_0} \right)_{\max.} = \frac{2}{3} - \frac{4\alpha}{9} \left\{ 1 - \sqrt{1 + \frac{3}{2\alpha}} \right\} \quad (14)$$

This means that for any probable value of  $\alpha$  the maximum occurs when about one-third of the material has been polymerised, so that the suggestion advanced in Part I. that the observed shift of the position of this maximum is to be attributed to the size of the final polymer requires modification. We shall return to this point later, but we may discuss here the case where the maximum occurs after more than  $\frac{1}{3}$  polymerisation. By an extension of the methods of Part I. it is easily shown that the velocity of a polymerisation chain in which the constants of the successive stages (after the first) decrease according to the law

$$k_r = \frac{K}{r^p} \quad (15)$$

is given approximately by

$$-\frac{dN}{dt} = \frac{K}{\nu^p(\nu - 1)^2} (N\nu - n_0)(n_0 - N) \quad (16)$$

so that the condition for the  $\left( \frac{dN}{dt} \sim N \right)$  curve to become parabolic is  $\nu \rightarrow \text{const.}$ , a condition which will be fulfilled for reactions in which a large steric factor is operative.

We now propose to consider some cases in which other methods of chain termination become important. It is evident that if the rate of propagation of the polymerisation chains is large compared with the rate of initiation, any factor which tends to deactivate the growing

polymer will become of great importance, and we may thus divide polymerisation processes roughly into three groups:

(i) The type already considered where the steric factor exerts the controlling influence on chain length.

(ii) Cases where the ratio of propagation rate to initiation rate is so large that the chain length is governed almost entirely by factors leading to deactivation.

(iii) Intermediate cases where both mechanisms play comparable parts.

A qualitative discussion of the various mechanisms which may lead to deactivation has been given by Rideal,<sup>4</sup> and the view that such a variety of processes may—under different circumstances—play an important part is supported by the apparent complexity of the phenomena described by the workers taking part in the recent Faraday Society General Discussion.<sup>5</sup> The quantitative application of these ideas has been commenced by Melville,<sup>6</sup> in a study of the photopolymerisation of acetylene and by Norrish and Carruthers,<sup>7</sup> who have investigated the thermal polymerisation of formaldehyde in the presence of formic acid. In the following pages we shall discuss the behaviour of polymerisation processes in which the growth of the chains is terminated in various ways, and consider the application of the results to experiment.

## Case II. The Chains are Terminated by "Spontaneous" Deactivation.

Under this heading we may include any mechanism which is independent of collisions with other reactants, such as a reversion of the active group to a stable inactive form, or the collision of an active group with the wall.

The growth of the polymer is represented as before by reactions (3), while its termination occurs by:

The velocity constants of these reactions (17) we shall assume to be constant and to be related to those of reactions (3) by the factor  $\lambda n_0$ :

$$k_r = K \cdot \lambda n_0 \quad (18)$$

The rates of formation of the various molecular species can now be written down and the total rate of reaction obtained by the relationship

$$\frac{dN}{dt} = \frac{d}{dt}(n_1 + n_1') + \frac{1}{2} \frac{d}{dt}(n_2 + n_2') + \dots + \frac{1}{r} \frac{d}{dt}(n_r + n_r') + \dots \quad (19)$$

A simplification can be made at this point, since our discussion is to be confined to cases where the rate of chain initiation is small compared with the rate of termination ( $\alpha \ll \lambda$ ) and the chain length is thus

<sup>4</sup> Rideal, *Trans. Faraday Soc.*, 1936, **32**, 3.

<sup>5</sup> General Discussion on Polymerisation, *ibid.*, 1936, **32**, 1-412.

<sup>6</sup> Melville, *ibid.*, 1936, **32**, 258; cf. also Rideal, *P.R.S.*, 1934, **146A**, 268.

<sup>7</sup> Norrish and Carruthers, *Trans. Faraday Soc.*, 1936, **32**, 195.

governed by the latter process. It is therefore permissible to write stationary state equations for the concentrations of all the active bodies involved, so that (19) reduces to:

$$\frac{dN}{dt} = \frac{dn_1}{dt} + \frac{1}{2} \frac{dn_2}{dt} + \dots + \frac{1}{r} \frac{dn_r}{dt} + \dots \quad (20)$$

It is easily seen from (3) and (17) that, for  $r \geq 2$

$$\frac{dn_r}{dt} = K n_r' \cdot \lambda n_0 \quad (21)$$

$$\frac{dn_1}{dt} = K \left[ \lambda n_0 n_1' - \alpha n_0 n_1 - n_1 \left( n_1' + \frac{1}{2} n_2' + \dots + \frac{1}{r} n_r' + \dots \right) \right] \quad (22)$$

$$\text{whence} \quad \frac{dN}{dt} = -K n_1 \left[ \alpha n_0 + \left( 1 - \frac{\lambda n_0}{n_1} \right) \sum_{r=1}^{\infty} \frac{1}{r} n_r' \right] \quad (23)$$

To evaluate  $\sum_r \frac{1}{r} n_r'$  we write down the stationary state equations for all the active bodies, and sum:

$$\left. \begin{aligned} \frac{dn_1'}{dt} &= 0 & \therefore \alpha n_0 n_1 &= n_1' (n_1 + \lambda n_0) \\ \frac{dn_2'}{dt} &= 0 & \therefore n_1 n_1' &= \frac{1}{2} n_2' (n_1 + \lambda n_0) \\ &\vdots & & \\ \frac{dn_r'}{dt} &= 0 & \therefore \frac{1}{r-1} n_1 n_{r-1}' &= \frac{1}{r} n_r' (n_1 + \lambda n_0) \\ &\vdots & & \end{aligned} \right\} \quad (24)$$

$$\text{Adding} \quad \alpha n_0 n_1 + n_1 \sum_{r=1}^{\infty} \frac{1}{r} n_r' = (n_1 + \lambda n_0) \sum_{r=1}^{\infty} \frac{1}{r} n_r'$$

$$\text{whence} \quad \sum_{r=1}^{\infty} \frac{1}{r} n_r' = \frac{\alpha}{\lambda} n_1 \quad (25)$$

Combining this equation with (23) we find

$$-\frac{dN}{dt} = \frac{\alpha}{\lambda} K n_1^2 \quad (26)$$

or, in terms of  $x$ ,

$$\frac{dx}{dt} = \frac{\alpha}{\lambda} K n_0 (1-x)^2 \left( \frac{1+2\lambda-x}{1+\lambda-x} \right) \quad (26a)$$

We next wish to know how the mean chain length  $\nu$  of the polymerised fraction varies during the reaction. We have, by differentiation of equation (9)

$$-\frac{d\nu}{dn_1} = \frac{\nu}{n_0 - n_1} - \frac{\nu^2}{n_0 - n_1} \left( 1 - \frac{dN}{dn_1} \right) \quad (27)$$

$$\text{Then} \quad 1 - \frac{dN}{dn_1} = 1 - \frac{dN/dt}{dn_1/dt} = \frac{\lambda n_0}{n_1 + 2\lambda n_0} \quad (28)$$

Substituting from (28) in (27) and integrating we obtain finally

$$\nu = \frac{n_0 - n_1}{\lambda n_0 \ln \left\{ \frac{n_0 + 2\lambda n_0}{n_1 + 2\lambda n_0} \right\}} \quad (29)$$

### Case III. The Chains are Terminated by Collision with a Molecule of Monomer.

Analysis of the kinetic data obtained in the photopolymerisation of acetylene has been shown by Melville<sup>6</sup> to lead to the conclusion that collision between a growing polymer and a molecule of monomer may lead either to chain growth or deactivation, and a similar mechanism has been found by Norrish and Carruthers<sup>7</sup> to be operative in the polymerisation of formaldehyde. It would thus appear that this may be a mechanism which is frequently of importance, and we shall now proceed to a kinetic analysis.

Chain growth is represented as before by (3), but (17) must be replaced by

The velocity constant of any of these reactions (assumed the same) is given by

$$k_r'' = \gamma \cdot K \quad (30a)$$

where  $\gamma$  is a constant.

The analysis follows exactly the same lines as before, and it is found that

$$-\frac{dN}{dt} = \frac{\alpha K n_0 n_1}{\gamma} \quad (31)$$

or, in terms of  $x$ ,

$$\frac{dx}{dt} = \frac{\alpha(1 + 2\gamma)}{\gamma(1 + \gamma)} K n_0 (1 - x) \quad (31a)$$

$$v = 2 + \frac{1}{\gamma} \quad (32)$$

This last equation is identical with the result found by Melville.

### Case IV. Partial Deactivation.

In Cases II. and III. we have assumed that the size of the polymer is controlled completely by the deactivation process, while case I. on the other hand neglects this entirely. It is clear that intermediate cases must exist and indeed are probably very general. The problem now becomes much more difficult since no stationary state equations can be employed, but by making use of the "Z" function (equation (5)) the mechanism of Case III. can be re-investigated, as follows:

It is easily shown that

$$-\frac{dN}{dZ} = n_1' + \frac{1}{2}n_2' + \frac{1}{3}n_3' + \dots \quad (33)$$

where the various terms are given by

$$\left. \begin{array}{l} \frac{dn_1'}{dZ} = \alpha n_0 - (1 + \gamma)n_1' \\ \frac{1}{2} \frac{dn_2'}{dZ} = n_1' - \frac{1}{2}(1 + \gamma)n_2' \\ \vdots \\ \frac{1}{r} \frac{dn_r'}{dZ} = \frac{n_{r-1}'}{r-1} - \frac{1 + \gamma}{r} n_r' \end{array} \right\} \quad (34)$$

whence

$$\frac{1}{r}n_r' = \frac{\alpha n_0}{(1+\gamma)^r} \left[ 1 - \left\{ 1 + Z(1+\gamma) + \frac{Z^2}{2}(1+\gamma)^2 + \dots + \frac{Z^{r-1}}{(r-1)!}(1+\gamma)^{r-1} \right\} e^{-(1+\gamma)Z} \right] \quad (35)$$

Combining equations (33) and (35) and summing to  $r \rightarrow \infty$

$$-\frac{dN}{dZ} = \frac{\alpha n_0}{\gamma(1+\gamma)} (1 - e^{-\gamma Z}) \quad (36)$$

whence 
$$n_0 - N = \frac{\alpha n_0}{\gamma(1+\gamma)} \left\{ Z - \frac{1}{\gamma}(1 - e^{-\gamma Z}) \right\} \quad (37)$$

Similarly 
$$-\frac{dn_1}{dZ} = \frac{\alpha n_0}{\gamma} \left( 1 - \frac{e^{-\gamma Z}}{1+\gamma} \right) \quad (38)$$

*Polymerisation with Spontaneous Deactivation.*  
 $I, \bar{x}, \lambda = 0.01$   
 $I, \beta \frac{d}{dn_0} = 0.01$  [Cf. part II]

FIG. 1.

and 
$$n_0 - n_1 = \frac{\alpha n_0}{\gamma} \left\{ Z - \frac{1}{\gamma(1+\gamma)} (1 - e^{-\gamma Z}) \right\} \quad (39)$$

Subtracting (39) from (37) and dividing into (39) we can find the chain length  $\nu$  from equation (9). The result is

$$\nu = \frac{1+\gamma}{\gamma} \left\{ 1 - \frac{1 - e^{-\gamma Z}}{Z\gamma(1+\gamma)} \right\} \quad (40)$$

Equations (36) and (38) can now be combined with (5) to give the velocity of polymerisation as a function of  $Z$ :

$$-\frac{dN}{dt} = \frac{\alpha K n_0 n_1}{\gamma(1+\gamma)} (1 - e^{-\gamma Z}) \quad (41)$$

$$\frac{dx}{dt} = \frac{\alpha K n_0^2}{\gamma} (1-x) \left( 1 - \frac{e^{-\gamma Z}}{1+\gamma} \right) \quad (42)$$

By further differentiation the condition for the velocity to be a maximum

is: 
$$2e^{-2\gamma Z} - \left\{ 3 + \gamma + \gamma(1+\gamma) \left( \frac{\gamma}{\alpha} - Z \right) \right\} e^{-\gamma Z} + (1+\gamma) = 0 \quad (43)$$

These equations (5, 36-43) give a complete description of the behaviour of the system in terms of the parameter  $Z$ .

### Summary of Results and Experimental Application.

In Figs. 1 to 3 are given plots of the velocity and chain length as functions of  $N/N_0$  for the various mechanisms discussed above.\* These curves have been derived from the theoretical equations as follows:

\* Figs. 1 and 2 include also curves showing the effects of inhibitors. The equations on which these are based are derived in Part III. (below).

*Figs. 1 and 2.*—For a given value of  $n_1$ ,  $dN/dt$  is calculated from equations (26), (31) and  $\nu$  from (29) and (32) while the corresponding values of  $N$  are found from (9) by putting in the derived values of  $\nu$ .

*Fig. 3.*—Curves A are obtained directly from equations (11), (13). Curves B, C, D are obtained by calculating  $dN/dt$ ,  $\nu$  and  $N$  for given values of  $Z$  by means of equations (41), (40), (37).

The principal features of the different curves will be evident on inspection. When deactivation is the controlling factor of the process the induction period vanishes\* and the curve becomes pseudo bimolecular (spontaneous deactivation) or unimolecular (deactivation by monomer) while the mean chain length remains constant in the latter case and decreases during the reaction in the former. In all the curves of Fig. 3 an induction period is evident, and the chain length of the polymer increases progressively. In these curves we may note further that the fraction polymerised before the maximum velocity is attained decreases progressively as the deactivation reaction becomes increasingly important. We have thus a complete explanation of the variation of induction period from zero (strong deactivation) to  $\frac{1}{2}$  reaction (no deactivation; no steric factor) and finally to  $\frac{1}{2}$  reaction (large steric factor).

We may now turn to consider the application of these results, and we note first that we can measure experimentally:

1. The velocity of polymerisation.
2. The mean chain length of the polymer at various stages of reaction.
3. Possibly also the distribution of molecular sizes in the polymer.†

From 1 we can plot a gradient curve ( $\frac{dN}{dt} \sim N$ ) and thence obtain

- (a) the position and magnitude of maximum velocity;
- (b) if the induction period is short or absent the shape of the later part of the curve, and thence a uni- or bi-molecular constant.

These observations suffice to enable us to decide by inspection what mechanism is operative, and thus by application of the equations given above to obtain the values of the various constants. The procedure may be illustrated by reference to specific examples taken from published work:

1. It is scarcely surprising to find no completely satisfactory example of the simplest Case I. (no deactivation; zero steric factor) although Dostal and Mark<sup>2(b)</sup> have shown that some rather fragmentary data for the early stages in the polymerisation of styrene can be adequately represented by this type of curve, but since the chain length has not been measured we cannot find  $\alpha$  and  $Kn_0$  separately. From the published curve (Fig. 9)  $\left(\frac{dx}{dt}\right)_{\max.}$  is about 1.8, and putting  $x_{\max.} = \frac{1}{2}$  it is easily found that

$$Kn_0\sqrt{\alpha} \cong 3.2.$$

\* This, of course, is not strictly true. It is more accurate to say that the induction period is too short to be detected experimentally.

† Cf. Schultz, *Z. physik. Chem.*, 1935, **30B**, 379. It should be pointed out that the distribution depends on the mechanism, and Schultz' calculation is therefore only valid for the special mechanism he considers. His results may be compared for ex. with the curves given by Dostal and Mark<sup>2</sup> and Carothers (*Trans. Faraday Soc.*, 1936, **32**, 39).

2. Numerous examples of reactions in which  $x_{\max.} > \frac{1}{2}$  are given by polymerisation of monolayers of oxidised maleic anhydride  $\beta$ -eleostearin.<sup>8</sup> It is probably best in these cases to adhere to the proposal to describe such reactions by the Semenoff equation (*cf.* ref. 8 and Part I.).

3. Examples of pseudo bimolecular reactions, which we can interpret as showing spontaneous deactivation, are given by the polymerisation of indene<sup>9</sup> and  $\beta\gamma$  dimethyl butadiene.<sup>10</sup> In both cases a short induction period is found, the maximum occurring after about 18 per cent. polymerisation in the former case, 12 per cent. in the latter; the respective bimolecular constants (in  $\text{secs.}^{-1}/\text{per cent.}$ ) being  $1.8 \times 10^{-8}$ ;  $1.25 \times 10^{-5}$ . These measure  $\alpha K/\lambda$  but as the general case of spontaneous deactivation with an induction period has not been worked out, we cannot determine these three constants separately.

*Polymerisation of Isosafrole at 258°C [Whitby & Katz].*

◦ *Experimental Points*

A. Calculated from  $\alpha = 5.7 \times 10^{-4}$ ,  $\gamma = 0.2$ ,  $K\eta_0 = 2.2 \times 10^{-6} \text{secs.}^{-1}$

B. Unimolecular Constant  $5.7 \times 10^{-6} \text{secs.}^{-1}$  Chalmers.

C. Zero steric factor; no deactivation  $\alpha = 2.5 \times 10^{-6}$ ;  $\gamma = 0$ .

FIG. 4.

4. Chalmers<sup>11</sup> has collected the results of a number of polymerisation reactions which appear to be pseudo-unimolecular, and although a closer examination shows some of these to be better represented by other types of equation, there remain several examples of this type (deactivation by monomer). Among these may be mentioned the thermal<sup>12</sup> and photo<sup>13</sup> polymerisation of vinyl acetate, for which the velocity constants are respectively  $1.83 \times 10^{-5}$  (at 82° C.) and  $5.8 \times 10^{-5}$ . For the latter case the quantum efficiency and inhibitory effect of pyrogallol suggest a chain length of the order of 1000, so that  $\gamma \cong 10^{-3}$ , and  $(\alpha K\eta_0) \cong 6 \times 10^{-8}$ .

initiating the reaction chains. Jeu and Alyea, although also studying photo-polymerisation, avoided this difficulty by employing a band of the spectrum which was not absorbed by the inhibitors they investigated.

Empirically, their results can be expressed in the form:  $k = \frac{k_0}{1 + \alpha c}$ ,

where  $k_0$  is the velocity constant in the absence of inhibitor,

$k$  is the velocity constant when the inhibitor concentration is  $c$ ,

$\alpha$  is a specific constant for the inhibitor.

On the analogy of the Christiansen-Kramers energy chain, this was written in the form:

$$k = \frac{k_1 k_2}{k_3 + k_4 c}$$

where  $k_1$ ,  $k_2$ ,  $k_3$  and  $k_4$  are the respective velocity constants for initiation, propagation, spontaneous termination, and inhibition of the chains. Jeu and Alyea then proceeded further to estimate the chain length  $\nu$ , assuming by analogy that this was given by:

$$\nu = \frac{k_2}{k_3 + k_4 c}$$

The problem has been discussed by Chalmers,<sup>3</sup> and the same form of equation deduced by a simple argument based on a stationary state equation for the activated monomer in a polymerisation chain. Chalmers arrived at the conclusion that  $\frac{k_2}{k_3 + k_4 c}$  is to be interpreted, not as the chain length of the polymer, but as the mean life of the activated monomer. Unfortunately, his derivation neglects entirely the effect of the inhibitor on the activated polymeric molecules, and provides no mechanism of chain termination, so that its physical basis is doubtful.

Notwithstanding the many interesting features exhibited by catalysed polymerisation processes there would appear to be as yet no reliable quantitative data for the effect of catalysts on polymerisation velocity, while the mechanism of catalysis remains a matter of dispute. Qualitative and semi-quantitative observations reveal wide differences of behaviour between different types of catalytic polymerisation, and no general explanation of the phenomenon has yet been given.

In this paper we shall investigate the effects of inhibitors and catalysts on polymerisation processes proceeding by mechanisms discussed in Part II. (above).

## I. Inhibitors.

We consider a polymerisation chain whose growth is described by equation (3) of Part II.; the termination of the chain by an inhibitor X may then be represented by:

\* Chalmers, *J.A.C.S.*, 1934, **56**, 912.

\* The numbering of the equations is continued from Part II. to facilitate reference. These equations assume that the inhibitor does not undergo chemical change during the deactivation process.

The velocity constants  $k_r'''$  of these reactions are assumed to be the same, and are given by :

$$k_r''' = K \cdot \beta \quad . \quad . \quad . \quad (46)$$

where  $\beta$  is a constant.

If the number of molecules of inhibitor present is  $c$  its concentration is  $c/n_0$  moles/mole of polymerisable material.

We are now in a position to examine the effect of introducing this additional chain-breaking mechanism to reactions in which the normal mechanism of deactivation is spontaneous (Case II.) or collision with monomer (Case III.). The revised equations for the velocity and polymer size are found to be :

**Case II., Spontaneous Deactivation.** (Cf. equations (26), (29).)

$$-\frac{dN}{dt} = \frac{\alpha K n_0 n_1^2}{\lambda n_0 + \beta c} \quad . \quad . \quad . \quad (47)$$

$$v = \frac{n_0 - n_1}{(\lambda n_0 + \beta c) \ln \left\{ \frac{n_0 + 2(\lambda n_0 + \beta c)}{n_1 + 2(\lambda n_1 + \beta c)} \right\}} \quad . \quad . \quad (48)$$

**Case III., Collision with Monomer.** (Cf. equations (31), (32).)

$$-\frac{dN}{dt} = \frac{\alpha K n_0 n_1^2}{\gamma n_1 + \beta c} \quad . \quad . \quad . \quad (49)$$

$$v = \frac{(1 + 2\gamma)(n_0 - n_1)}{\gamma \left[ (n_0 - n_1) + \frac{\beta c}{\gamma(1 + 2\gamma)} \ln \left\{ \frac{n_0 + \frac{2\beta c}{1 + 2\gamma}}{n_1 + \frac{2\beta c}{1 + 2\gamma}} \right\} \right]} \quad . \quad (50)$$

The effect of an inhibitor on the reaction velocity may be expressed by the equation :

$$v_0 = v(1 + p c/n_0) \quad . \quad . \quad . \quad (51)$$

where  $v$ ,  $v_0$  are the velocities with and without inhibitor.  $p$  is given for the two cases by :

$$p_{II} = \beta/\lambda \quad . \quad . \quad . \quad (52)$$

$$p_{III} = \beta n_0/\gamma n_1 \quad . \quad . \quad . \quad (53)$$

Equation (51) is identical with the empirical expression if  $p$  is a constant : this condition is clearly fulfilled by  $p_{II}$  but not by  $p_{III}$ , except (approximately) for small ranges of  $n_1$ .

The use made by Jeu and Alyea<sup>1</sup> of data on the effect of inhibitors to estimate the polymer size requires further that the velocity should be directly proportional to the chain length. This has been tested for the constants employed in calculating the curves of Figs. 1 and 2 (Part II.) by comparing  $v_c/v_0$  with  $v_c/v_0$  for various values of  $N$ , with the following results, shown in Table I.

It is clear from the above that the relationship  $\frac{v_c}{v_0} = \frac{v_c}{v_0}$  holds with sufficient accuracy when the uninhibited reaction is controlled by spontaneous deactivation, but is valid only for the early stages of a reaction

TABLE I.—EFFECT OF INHIBITOR ON VELOCITY AND CHAIN LENGTH.

$N/n_0$	$v_0$	$v_c$	$v_0$	$v_c$	$v_c/v_0$	$v_c/v_0$
<b>Spontaneous Deactivation.</b>

0.7	48.7	23.9	85.8	43.8	0.49	0.51
0.5	24.3	12.0	73.7	37.6	0.49	0.51
0.2	3.5	1.5	50.6	25.8	0.43	0.51
<b>Deactivation by Monomer.</b>						
1.0	100.0	52.5	102.0	52.0	0.525	0.51
0.7	69.7	30.0	102.0	47.0	0.46	0.47
0.5	49.7	16.1	102.0	43.7	0.33	0.43
0.2	19.3	2.6	102.0	34.7	0.14	0.34

controlled normally by deactivation by monomer. This conclusion is of especial interest, since it has already been shown in Part II. that the photo-polymerisation of vinyl acetate studied by Jeu and Alyea<sup>1</sup> probably belongs to the latter class. Inspection of the results quoted by these workers shows that the experimental observations are very well represented by the equation valid for ordinary chain reactions, but there is a slight tendency for the observed values of the fraction polymerised ( $x$ ) to be higher than the calculated ones at the highest inhibitor concentration ( $c$ ). A plot of  $1/x \sim c$ , where  $x$  is measured always after the same time of reaction, thus tends to be concave towards the  $c$ -axis, whereas Jeu and Alyea's relationship gives a straight line. A relationship between  $x$  and  $c$  can be derived from the analysis given above, in the form:

$$\frac{1 + 2\gamma}{2 - x} + \frac{\beta c}{1 - x} - \frac{1}{(1 + 2\gamma)(2 - x) + 4\beta c} = \frac{k\gamma(1 + \gamma)}{x(1 + 2\gamma)} \quad (54)$$

where  $k$  is to be found from the rate of the uninhibited reaction. (A slight simplification has been made by putting

$$\ln 1/(1 - x) = 2x/(2 - x).$$

Taking  $\gamma = 0.001$  (cf. Part II.) a plot of  $1/x \sim c$  can be made by choosing  $\beta$  so as to fit a single experimental point.  $\beta = 2.35$  was found to give a good fit of Jeu and Alyea's data for pyrogallol, and gave a ( $1/x \sim c$ ) curve slightly concave towards the  $c$ -axis. The deviation from linearity is, however, too small to be significant over the range covered by the experiments ( $x \geq 0.4$ ), although it would become a large correction if the range was extended to larger values of  $x$ . No decisive test of the theoretical treatment is therefore possible from existing data.

## II. Catalysts.

We turn now to the consideration of catalysed polymerisation, and clearly the simplest possible mechanism is the initiation of chains by the catalyst, a case already considered by Dostal and Mark.<sup>4</sup> The precise manner in which this catalysis occurs may vary in different reactions. Thus Conant and Peterson<sup>5</sup> suppose that in the polymerisation of isoprene and butyraldehyde the first process is the formation of a peroxide which then dissociates to give an activated monomer which initiates a polymerisation chain. A similar mechanism has been proposed by Dunstan

<sup>4</sup> Dostal and Mark, *Trans. Faraday Soc.*, 1930, **32**, 54.

<sup>5</sup> Conant and Peterson, *J.A.C.S.*, 1930, **52**, 1659; 1932, **54**, 628.

and Ipatieff<sup>6</sup> for the catalytic effect of phosphoric acid on the polymerisation of propylene. Of a different type is the suggestion made by Norrish and Carruthers<sup>7</sup> as to the effect of formic acid in initiating polyoxymethylene chains, which is formulated thus:

A very simple formal treatment of this type of reaction can be given, as it is only necessary to add to the equations already given in Part II. the further one :

the rate of which is  $\rho K c n_1$ , where  $\rho$  is a constant and  $c$  is the number of molecules of catalyst. The first effect of this addition is to increase the polymerisation velocity by a factor

$$v = v_0(1 + \rho c / \alpha n_0) \quad (56)$$

The chain length is independent of the rate of chain initiation in Cases II. and III. (Part II.), but not in Cases I. and IV. In these mechanisms the chain length will be decreased by the catalyst, the magnitude of the effect being readily determinable by replacing  $\alpha$  in equations (13) and (39) by  $\alpha^*$  where

$$\alpha^* = \alpha + \rho \cdot \frac{c}{n_0} \quad . \quad . \quad . \quad (57)$$

For Case I. (no steric factor, no deactivation), we obtain, by combining (57) with (13),

$$\frac{v_c - 1}{v_0 - 1} = \sqrt{\frac{v_0}{v_c}} \quad (58)$$

This simple mechanism is inadequate to account for the complexity of the results observed, for in general the effect of catalysts on chain length may be in either direction. Thus styrene which by spontaneous polymerisation yields high polymers, may in the presence of catalysts be converted into distyrene.<sup>8</sup> Dimethyl ketene, on the other hand, gives only a dimer spontaneously, but can be induced to give long chain products by addition of catalysts.<sup>9</sup> The decrease of chain length is readily understood if the rate of chain initiation is a controlling factor, and could equally be brought about by the catalyst acting also as a chain breaking inhibitor. The explanation of increased chain length is by no means so clear, apart from a few cases where chain branching may be possible (*cf.* Norrish and Carruthers<sup>7</sup>). It is suggested that the explanation of this phenomenon must be sought in the formation of unstable complexes between the catalyst and the polymerising material. The cumulative evidence for the existence of such complexes is strong, and it has been shown by Staudinger and Bruson<sup>9</sup> that the catalytic activity of the halides of some non-metals runs closely parallel with their tendency to form complexes. Thus  $\text{BF}_3$ ,  $\text{SnCl}_4$ , and  $\text{AlCl}_3$ , which are known to form complexes readily, are catalysts, while  $\text{SiCl}_4$  and  $\text{POCl}_3$  show neither catalytic activity nor tendency to form complexes. The suggestion that

\* Dunstan and Ipatietti, *Trans. Faraday Soc.*, 1936, **32**, 227.

<sup>7</sup> Norrish and Carruthers, *ibid.*, 1936, 32, 195.

\* Stobbe and Posnjak, *Ann.*, 1910, 311, 292.

\* Staudinger and Bruson, *ibid.*, 1926, 447, 110.

complexes are formed as the initial stage of catalysed polymerisation has also been put forward by Abkin and Medvedev<sup>10</sup> for the catalysis by sodium of the polymerisation of 1 : 3 butadiene, and by Chalmers<sup>11</sup> for the polymerisation of vinyl ethers in the presence of iodine. In the polymerisation of monolayers of oxidised drying oils there is also direct evidence from surface potential measurements that cobalt, which acts as a polymerisation catalyst, forms a complex with the film.<sup>12</sup> We have next to discuss the general mechanism by which the complex catalyses the polymerisation process, and two alternative suggestions have been put forward. Chalmers<sup>3</sup> and Bergmann<sup>13</sup> formulate the addition of catalyst to reactant in such a way that a free valency is produced. Thus the polymerisation of 1 : 3 butadiene by sodium would be written :

Abkin and Medvedev,<sup>10</sup> on the other hand, formulate this reaction as

Neither of these proposals is quite satisfactory. In the former case, it is impossible to imagine the influence of the catalyst extending more than a few links, so that the active group is the same as in the uncatalysed reaction, and the mechanism reduces formally to the one already considered. On the other hand, the alternative explanation involves two apparent difficulties : (i) the necessity for migration of the catalyst to the active end of the polymer at every step in the reaction, and (ii) the reaction becomes virtually a "stepwise" reaction, which has been shown by Chalmers<sup>3</sup> to be incapable of yielding long chain products. This dilemma may be avoided by the assumption of a mechanism similar to the well-known migration of atoms incident on the face of a growing crystal to the end of the crystal, where they take part in the building up process. It has been suggested by de Boer<sup>14</sup> that this type of mechanism may be operative in the normal building up of polymers, and thus account for the very high rates of chain propagation. We may thus visualise the catalyst as remaining in association with the active portion of the growing polymer for a length of time which will vary with the natures of the reactant and catalyst. If the time is very short, we have virtually a collision mechanism, which reduces to the previous case ; a long time of association gives us complex formation in which the catalyst remains at the active and growing point. This latter case is examined in the next section.

## IIa. Catalysis by Complex Formation.

We shall consider the catalysis of a chain in which termination normally occurs by collision with a monomer, and shall have in addition to the reactions represented by equations (3) and (30) the following processes :

<sup>10</sup> Abkin and Medvedev, *Trans. Faraday Soc.*, 1936, **32**, 286.

<sup>11</sup> Chalmers, *Can. J. Res.*, 1932, **7**, 476.

<sup>12</sup> Gee and Rideal, *Proc. Roy. Soc.* 1935, **153A**, 116; Gee, *ibid.* 1935, **153A**, 129; *Trans. Faraday Soc.*, 1936, **32**, 187.

<sup>13</sup> Bergmann, *ibid.*, 1936, **32**, 295.

<sup>14</sup> de Boer, *ibid.*, 1936, **32**, 69.

Equation (59) represents the formation of the initial complex, and its velocity constant is written as :

$$k^{IV} = K\alpha'c \quad (62)$$

Equations (60) give the building up of polymeric complexes, this process being terminated by dissociation of the complex, as in (61). The rates of these two processes are respectively

$$k_r^V = K \cdot \sigma \quad (63)$$

$$k_r^{VI} = K\lambda'n_0 \quad (64)$$

We have this time a further series of compounds (the complexes) whose concentrations are denoted by  $n'_{re}$ , and can be evaluated by writing down the appropriate stationary state equations. A further complication arises from the fact that the effective catalyst concentration depends on the amount of complex present and is therefore not constant. If  $c/n_0$ ,  $c_e/n_0$  are the total and effective (uncombined) catalyst concentrations, then

$$c = c_e + \sum_{r=1}^{\infty} \frac{1}{r} n'_{re} \quad (65)$$

whence

$$c_e = \frac{\lambda'n_0c}{\lambda'n_0 + \alpha'n_1} \quad (66)$$

We may now proceed to derive the velocity equation in the usual way, and the result is :

$$-\frac{dN}{dt} = K \left[ \frac{\alpha n_0 n_1}{\gamma} + \frac{\sigma \alpha' c n_1^2}{\lambda' n_0 + \alpha' n_1} \right] \quad (67)$$

The expression representing the variation of chain length is excessively complicated and only a formal solution will be given. By putting in numerical values of the constants  $(1 - dN/dn_1)$  can be obtained in the form :

$$1 - \frac{dN}{dn_1} = \frac{An_0^2 - Bn_0(n_0 - n_1) + D(n_0 - n_1)^2}{En_0^2 - Fn_0(n_0 - n_1) + (n_0 - n_1)^2} \quad (68)$$

where  $A$ ,  $B$ ,  $D$ ,  $E$  and  $F$  are numerical constants.

Combining with equation (27) an expression is obtained which can be integrated to give a solution of the form :

$$v = \frac{a(n_0 - n_1)}{(n_0 - n_1) + bn_0 \log \left\{ \frac{dn_0}{(d-1)n_0 + n_1} \right\} + en_0 \log \left\{ \frac{fn_0}{(f-1)n_0 + n_1} \right\}} \quad (69)$$

where  $a, b, d, e$  and  $f$  are further numerical constants which are related to the former constants by the following equations:

$$\left. \begin{aligned} a &= 1/D \\ b) \\ e) &= 1.15 \left\{ (B/D - F) \pm \frac{BF - 2A}{D} + 2E - F^2 \right\} \\ d) \\ f) &= 0.5 (F \pm \sqrt{F^2 - 4E}) \end{aligned} \right\} \quad (70)$$

*Catalysis by Complex formation*

I  $\alpha = 10^{-6}$ ;  $\gamma = 10^{-2}$ ;  $c = 0$

II  $\alpha = 10^{-8}$ ;  $\gamma = 10^{-4}$ ;  $\frac{c}{n_0} = 10^{-2}$ ;  $\sigma = 0.1$ ;  $\lambda^1 = 10^{-3}$ ;  $\alpha^1 = 0.1$ .

III  $\alpha = 10^{-6}$ ;  $\gamma = 10^{-4}$ ;  $\frac{c}{n_0} = 10^{-2}$ ;  $\sigma = 1$ ;  $\lambda^1 = 10^{-6}$ ;  $\alpha^1 = 0.1$ .

FIG. 5.

In Fig. 5 plots are given of  $(dN/dt \sim N)$  and  $(v \sim N)$  calculated for various values of the constants. It is evident from equation (67) that the catalytic effect must always be positive, but it is to be noted from the figure that this may be associated with either increase or decrease of the polymer size, so that this mechanism is able to include all the observed facts.

### Summary.

The effect of an inhibitor on the velocity of a polymerisation reaction and the size of the polymers produced is examined, and it is shown that the usual assumption that these are diminished in the same ratio is not strictly accurate, but is a good approximation in the early stages of the reaction.

The mechanism of catalysis is discussed, and two possibilities are analysed in detail:

(i) The catalyst initiates chain centres.

(ii) The catalyst forms a reactive complex.

It is shown that the latter is capable of explaining all the experimental observations.

## THE PHOTOCHEMISTRY OF NITRITES, NITRATES, AND NITRO COMPOUNDS.

BY H. W. THOMPSON AND C. H. PURKIS.

*Received 13th January, 1936.*

Much attention has been paid in recent years to the photochemistry of molecules containing the chromophoric carbonyl group. With the exception of a few isolated measurements, particularly in reference to inorganic nitrates and nitrites, no corresponding studies have yet been reported for compounds containing the nitro or nitroso group, although the kinetics of the thermal decomposition of such compounds have been studied.<sup>1</sup> The spectrum and photochemical decomposition of nitrosyl chloride was examined by Kistiakowsky,<sup>2</sup> and the absorption spectra of nitroethane, ethyl nitrate and ethyl nitrite by Goodeve.<sup>3</sup> Krishnan and Guha<sup>4</sup> have recently made measurements on the absorption spectra of inorganic nitrates and nitrites, and Anderson, Crumpler and Hammick<sup>5</sup> have discussed measurements on the photochemistry of two organic nitroso compounds.

It seemed desirable to make a systematic study of these compounds. The choice of substances amenable to investigation in the vapour state has obvious advantages, of which perhaps the most important is the greater chance of being able to analyse the absorption spectra and correlate them with the photochemical measurements. We have therefore chosen in the first place methyl and ethyl nitrates, methyl and ethyl nitrites, and nitromethane and nitroethane. Measurements on formaldoxime  $\text{H}_2\text{C} = \text{N} \cdot \text{OH}$ , and other oximes and their ethers, are in progress. The present paper deals with the absorption spectra of the first series of

<sup>1</sup> Steacie and others, *J. Chem. Physics*, 1934, **2**, 345; 1935, **3**, 344.

<sup>2</sup> *J.A.C.S.*, 1930, **52**, 102.

<sup>3</sup> *Trans. Faraday Soc.*, 1934, **30**, 504.

<sup>4</sup> *Proc. Ind. Acad. Sci.*, 1934, **1A**, 242.

<sup>5</sup> *J.C.S.*, 1935, 1679.

compounds, in which an important difference is found from the results given by Goodeve.

### Experimental Method.

**Methyl nitrite** was prepared by the method of Bertoni,<sup>6</sup> by dropping amyl nitrite slowly on to methyl alcohol, heating the latter gently. The vapours given off were passed through a series of traps and water condensers and finally frozen out in a liquid air trap. The product was a greenish liquid. It was fractionated, and the middle fraction, which was completely volatile below 0° C., collected. The purity of this sample was tested by measurements of its vapour pressure and hence boiling-point. The data are given below. The extrapolated B. Pt. was -18° C., rather lower than the value given in International Critical Tables (-12° C.). Repetition with a fresh sample gave a similar result, from which it seems probable that the figure hitherto accepted is in error.

**Ethyl nitrite** was prepared by refluxing a commercial 15 per cent. solution in alcohol. The vapour was condensed in a trap of ice and salt, and then fractionated. Methyl nitrate was prepared by the method of Delépine,<sup>7</sup> by the action of methyl alcohol on nitric acid. The product boiled at 66°-66.5° C., and this was in accordance with vapour pressure measurements.

**Ethyl nitrate** was obtained by fractionation of British Drug Houses product. Nitromethane was a commercial product purified by first drying with calcium chloride and then fractionating. Nitroethane was a Kahlbaum product repurified by fractional distillation.

The spectra were measured on a Hilger quartz spectrograph E 315, and the bands found were subsequently examined on a 3 metre concave grating with Eagle mounting, giving in the first order a dispersion of about 4 Å. per mm. Ilford Special Rapid or Panchromatic plates were used. The continuous source was a hydrogen discharge tube. The vapours were contained in glass absorption tubes of various lengths, with plane polished quartz ends cemented on. In some cases an all-quartz absorption cell, wired and heated electrically, was used.

For the measurements of the vapour pressures of the various substances the apparatus was similar to that described by Thompson and Linnett.<sup>8</sup>

### Results.

(1) **The Vapour Pressures of Methyl Nitrate, Methyl Nitrite and Nitromethane.**—Goodeve<sup>9</sup> determined the vapour pressure curves for ethyl nitrate, ethyl nitrite and nitroethane, but no data are given in the literature for the corresponding methyl derivatives.

The data are summarised in Fig. 1.

For **nitromethane** the extrapolated B. Pt. is 100.8° C. (*International Critical Tables*, 101° C.) and  $\lambda = 8280$  Cals., giving the Trouton constant,  $\lambda/T_b$ , the Entropy Change at the boiling-point as 22.2. The results are represented by the equation,

$$\log_{10} p = -\frac{1800}{T} + 7.69.$$

With **methyl nitrate** the measured boiling-point is 66.5° C. (*Int. Crit. Tables*, 65°-66° C.) and  $\lambda = 7800$  Cals., so that  $\lambda/T_b = 23.0$ . The vapour pressure equation is

$$\log_{10} p = -\frac{1694}{T} + 7.85.$$

<sup>6</sup> *Gaz. Chim. Ital.*, 12, 438.

<sup>7</sup> *Trans. Faraday Soc.*, 1935, 31, 1743.

<sup>8</sup> *Bull. Soc. Chem.*, (3), 13, 1044.

<sup>9</sup> *Ibid.*, 1934, 30, 501.

The measured B. Pt. for methyl nitrite is  $-18^{\circ}\text{C}$ . (*Beilstein*  $-12^{\circ}\text{C}$ .),  $\lambda = 5000$  Cals. and  $\lambda/T_0 = 19.75$ . The equation for the vapour pressure is

$$\log_{10} p = -\frac{1098}{T} + 7.19.$$

It is evident that the degree of association of these compounds is not considerable.

FIG. 1.

## (2) The Absorption Spectra.

**Methyl Nitrate.**—With pressures of vapour 10-200 mm. in columns 10-50 cm. in length, absorption is continuous from a very indefinite long-wave limit at about 3000 Å. towards shorter wavelengths. The extinction coefficient does not vary uniformly with wavelength, the curve (not accurately measured) showing a point of inflexion at about 2500 Å.

**Ethyl Nitrate.**—The spectrum is closely similar to that of methyl nitrate, the long-wave limit and variation of extinction coefficient with wavelength being within limits the same. This result agrees with that of Goodeve.

**Nitromethane.**—Continuous absorption is very marked from a fairly sharp limit at about 2350 Å. towards shorter wavelengths. A much feeble continuous absorption extended to about 2500 Å.

**Nitroethane.**—Absorption is continuous from about 3000 Å. to shorter

(2) METHYL NITRITE

(3) METHYL NITRITE (High dispersion)

wavelengths with a maximum at 2700 Å. and minimum at 2450 Å. This result agrees with that of Goodeve.

**Ethyl and Methyl Nitrite.**—According to Goodeve, ethyl nitrite shows continuous absorption to shorter wavelengths from a threshold at about 4000 Å., with a maximum at about 3640 Å. and a shallow minimum at 3030 Å. Absorption increases uniformly from the minimum to shorter wavelengths.

Our measurements with this substance agree completely with the above, except that at lower pressures we have resolved the first region of absorption between 4000-3000 Å. into a system of bands. In view of the strict agreement between ourselves and Goodeve for the long-wave threshold maximum and minimum, it seemed unlikely that the bands were due to some impurity or other error. The discovery, however, that with methyl nitrite

FIG. 2.

a similar system of bands is obtained, but differing slightly in wavelength from those of the ethyl compound, is adequate proof of their being genuine. With absorbing columns 10-20 cm. in length the most satisfactory pressure range for developing the bands is 10-50 mm. Goodeve's failure to detect the bands may have been due either to the nature of the method used (spectrophotometric), or to the use of too high pressures, when they become merged into a continuum.

The bands of methyl nitrite are shown in the plate, and depicted diagrammatically in Fig. 2a. They cannot be said to degrade with certainty in either direction, are broad, and although diffuse, show some features suggestive of fine structure. Examination under higher dispersion, however, failed to develop this. The breadth of the bands indicated by Fig. 2 is estimated roughly at the lowest pressures required for their development. The plate also shows the corresponding bands for ethyl nitrite, and their

wave numbers are given in Fig. 2*b*. The intensities shown in Figs. 2*a* and 2*b* are not accurate and are only intended as a qualitative guide.

**Amyl Nitrite.**—The results with methyl and ethyl nitrites suggest that in passing from the lower to the higher alkyl derivatives the band system is displaced to the red. The spectrum of repurified amyl nitrite was accordingly examined. It proved to be within the limits of the measurements identical with that of ethyl nitrite. The wide difference in vapour pressure between ethyl and amyl nitrite makes it inconceivable that the identical features of the two spectra arise from error.

FIG. 3.

### Discussion.

For purpose of comparison Fig. 3 shows the rough qualitative course of the extinction coefficients of the various compounds with varying wavelength.

It is clear that in the case of nitrites there are two excited electronic

levels, one associated with the bands, the other with the continuum. There may also be two excited state levels with the nitrates and nitro compounds, but if so these levels must lie closer together and further from the ground state.

It is important if possible first to determine the localisation of the electronic jump, which, in the case of any given compound, may or may not be the same for the two levels. By analogy with other compounds, such as ethers, it is unlikely that the electronic jump occurs in the alkyl radical or the R—O— of the nitrites, and it would thus appear to involve excitation of electrons localised in the region of the  $N=O$  link. This result is also suggested from a comparison of the nitrites with the nitrates and nitro compounds. That the levels of the nitrites lie lower than those of the nitrates would not then be surprising, since two electrons of the nitrogen atom are not employed for valency purposes in the nitrites, and might be relatively easily excited.

The absence of a maximum in the continuum, and the marked effect of pressure upon the long wave-length limit, makes it impossible to assign a value to the quantum corresponding to this electronic transition. In the same way it has not so far been possible to determine the "origin" of the band systems of the nitrites; in passing from the methyl to the ethyl derivative, however, the electronic jump decreases somewhat in magnitude, but with higher homologues may reach a constant value.

The interval relationships between the bands suggest a vibration frequency in the excited state of about  $1000\text{ cm}^{-1}$ , with a high anharmonicity coefficient. The Raman spectra of alkyl nitrites are very complicated;<sup>10</sup> it is also impossible to say whether the vibrational frequencies are increased or diminished in the excited state; it is therefore impossible to correlate the marked observed frequency of about 1100 with any particular normal vibration of the molecule. The magnitude of this frequency, however, is consistent with its being connected with a valency vibration of the  $N=O$  link.

FIG. 4.

<sup>10</sup> Dadiou, Jele and Kohlrausch, *Wien. Ber.*, 1931, 140.

The intensity distribution in the band systems, together with the Franck-Condon Principle, suggest the interpretation described by Fig. 4, but the significance of two-dimensional potential energy diagrams in this case is uncertain. The broad nature of the bands, A, B, H, I, and J with methyl nitrite, and of A, B, C, D, H, and I for ethyl nitrite, is peculiar, and requires further study. If the bands are genuinely diffuse, this may arise by a predissociation brought about by intersection of potential energy curves in the manner shown in Fig. 4. On the other hand, the variation of intensity within individual bands suggests some definite rotational structure.

Krishnan and Guha<sup>4</sup> have suggested that in the case of inorganic nitrites the two excited levels are associated with the fission of an oxygen atom in two different states of excitation. The same hypothesis might apply to the two levels of the alkyl nitrites, but we do not regard this as likely. There is some similarity between the spectrum of nitrosyl chloride and the spectra of the alkyl nitrites. In the former case the electronic energy absorbed by the  $N=O$  group eventually leads to a splitting of the  $N-Cl$  link, although there is still some doubt whether the energy switch occurs in the primary act without the intervention of a collision with a second molecule. Similar switches of energy from a chromophoric group to other linkages in the molecule are now known, e.g. in the photochemical decomposition of aldehydes and ketones. It is probable that the electronic energy absorbed by alkyl nitrites first enters the  $N=O$  group and is later distributed into the other linkages before dissociation occurs. The latter may follow a rather complicated course.

Photochemical measurements will be described later, when values of the quantum efficiency for the decomposition with frequencies corresponding to each of the two absorption regions will be compared.

### Summary.

As a preliminary to photochemical work, the ultraviolet absorption spectra of methyl and ethyl nitrites, methyl and ethyl nitrates, and nitromethane and ethane in the vapour state have been measured. All except the nitrites show continuous absorption. The nitrites each have a system of diffuse bands in the near ultraviolet. The bands are not all of equal intensity, and some have a peculiar variation of intensity within themselves. A marked vibration interval in the excited state seems to be about  $1000\text{ cm}^{-1}$ . There appear in general to be two excited electronic levels, both probably involving excitation of electrons localised in the  $N=O$  chromophore. The significance of the results is discussed.

The vapour pressures of the various compounds over a wide range of temperature have been measured.

We thank the Government Grant Committee of the Royal Society for assistance in the purchase of apparatus.

# THE VAPOUR PRESSURES AND ASSOCIATION OF SOME METALLIC AND NON-METALLIC ALKYL.

BY H. W. THOMPSON AND J. W. LINNETT.

*Received 14th February, 1936.*

In the course of a recent study of the absorption spectra of a series of metallic and non-metallic alkyls, it was necessary to know the vapour pressures of these compounds, over a wide range of temperature. Such data, especially with regard to the metal alkyls, are almost completely lacking. The present paper summarises measurements with some of these compounds. In a previous paper we have given the results for the alkyl sulphides.<sup>1</sup> Estimates were then made of the Trouton constant for the various substances since these are a possible guide to the degree of association in the liquid or gaseous phase. It is now possible to review the values of this quantity for the alkyl derivatives of elements of Groups II-VII. of the Periodic Table, and to make deductions concerning the extent of association of compounds of this type.

The vapour pressures of the following substances have now been measured: zinc dimethyl, zinc diethyl, mercury dimethyl, mercury diethyl, tin tetramethyl, triethyl phosphine, trimethylamine, triethylamine, and methyl iodide. Each was purified by the same method as described for the spectroscopic work.<sup>2</sup>

## Experimental Method.

The vapour pressures were determined by using a Bourdon gauge as zero instrument against a mercury manometer. The arrangement of the apparatus is shown in the diagram. The substance was

FIG. 1.

<sup>1</sup> *Trans. Faraday Soc.*, 1935, **31**, 1743.

<sup>2</sup> Thompson and Linnett, *Proc. Roy. Soc.*, 1936, *in the press*.

enclosed in a glass bulb C, connected to the gauge B, which had a fine solid pointer, the tip of which was coated with white enamel. Pressures inside the gauge were balanced by regulation of the mercury manometer E, (11 mm. bore), through the tap at F, which could be opened either to an oil pump or to the atmosphere. A fine glass capillary G was fixed to the back of the cylindrical glass tube holding the gauge. This was the "zero" mark, superposition with the pointer being observed through a small microscope. The apparatus was wired and heated electrically to about 90° C., and the upper part of the gauge was enclosed in an electric furnace maintained at a constant temperature of about 90° C. The bulb C could be enclosed in a wide glass tube D, suitably lagged, in which liquids of different boiling-point could be refluxed. The temperature of the vapour was measured by a standard thermometer. The levels of E were read off on a cathetometer. In general the liquid to be studied was distilled into C from a tube attached at H, the latter then being sealed off by a constriction. A little of the substance was then pumped off at K, C was surrounded by liquid air, and the apparatus evacuated and sealed off at K. The difference in the levels of E when C was immersed in liquid air was taken as the barometric height.

Liquids used in the refluxing chamber D were acetone, chloroform, ethyl ether, benzene, methyl alcohol, etc., all boiling below about 80° C. Cooling baths of melting ice, melting benzene, or melting aniline were also used.

### Results.

(1) **Zinc Dimethyl.**—The measured vapour pressures at different temperatures were :—

$t^{\circ}\text{C.}$	— 6.2	0	5.5	16.6
$p$ mm.	91	125	154	248

The plot of  $\log_{10} p$  against  $1/T$  is a good straight line, which on extrapolation to 760 mm. gives a B.Pt. of 46.9° C. (*Int. Crit. Tab.* 46° C.). The line can be expressed by

$$\log_{10} p = -\frac{1486}{T} + 7.52.$$

The latent heat of evaporation,  $\lambda$ , is thus 6840 Cals. per Mol., and  $\lambda/T_b$ , the Trouton constant or Entropy Change at the B.Pt., has the value 21.4.

(2) **Mercury Dimethyl.**—The measured vapour pressures are :—

$t^{\circ}\text{C.}$	20.5	36.0	55.3	59.8	63.7	78.7
$p$ mm.	50	103	217	255	297	477

The plot of  $\log_{10} p$  against  $1/T$  is a satisfactory straight line, but at low temperatures there are indications of a slight curvature. The extrapolated B.Pt. is 93.2° C. (recorded value 93°-96° C.). The line can be expressed by

$$\log_{10} p = -\frac{1720}{T} + 7.575$$

the latent heat  $\lambda = 7910$  Cals., and  $\lambda/T_b = 21.6$ .

(3) **Zinc Diethyl.**—The measured values are :—

$t^{\circ}\text{C.}$	17.2	35.0	55.3	60.4	64.8	79.8
$p$ mm.	13	32.5	73.0	90.0	108	196

The plot of  $\log_{10} p$  against  $1/T$  is a fairly good straight line, expressed by

$$\log_{10} p = -\frac{1910}{T} + 7.695$$

and giving an extrapolated B.Pt. 123° C. (recorded value 118° C.). Then  $\lambda = 8780$  Cals. and  $\lambda/T_b = 22.2$ .

(4) **Mercury Diethyl.**—The high boiling-point of this substance made it impossible to measure pressures in excess of about 50 mm. At 64° C.,  $p = 28$  mm., and at 80° C.  $p = 54$  mm. The recorded B.Pt. is 159° C. For these points the plot of  $\log_{10} p$  against  $1/T$  is linear, and represented by

$$\log_{10} p = -\frac{2200}{T} + 7.975$$

and  $\lambda_{10,120}$  Cals. Then  $\lambda/T_b = 23.4$ .

(5) **Tin Tetramethyl.**—The vapour pressures are :—

$t^\circ$ C.	18	35.5	55.8	59.5	64.0	78.9
$p$ mm.	87.5	172	376	425	492	787

With the exception of the value at the lowest temperature the plot of  $\log_{10} p$  against  $1/T$  is linear, and expressed by

$$\log_{10} p = -\frac{1620}{T} + 7.495.$$

The extrapolated B.Pt. is 77.7° C. (recorded value 76°–78° C.);  $\lambda = 7450$  Cals. and  $\lambda/T_b = 21.2$ .

(6) **Trimethylamine.**—The data are :—

$t^\circ$ C.	— 6.2	0	5.0	11.0
$p$ mm.	516	680	804	1018

The plot of  $\log_{10} p$  against  $1/T$  is roughly linear, giving a B.Pt. of 3.2° C., (Beilstein 3.2°–3.8° C.), and

$$\log_{10} p = -\frac{1265}{T} + 7.45,$$

giving  $\lambda = 5820$  Cals. and  $\lambda/T_b = 21.1$ .

(7) **Triethylamine.**—The vapour pressures are :—

$t^\circ$ C.	12.4	35.0	56.6	60.5	64.4
$p$ mm.	38	106	247	282	328

The plot  $\log_{10} p$  against  $1/T$  is a good straight line, expressed by

$$\log_{10} p = -\frac{1725}{T} + 7.625$$

and giving  $\lambda = 7930$  Cals. The extrapolated B.Pt. is 90.3° C. (*Int. Crit. Tables*, 89.5° C.). The value of  $\lambda/T_b = 21.9$ .

(8) **Triethyl Phosphine.**—The vapour pressures were :—

$t^\circ$ C.	18	36	55.1	59.3	63.5	78.2
$p$ mm.	10	24	50	70	79	143

There is good proportionality between  $\log_{10} p$  and  $1/T$ , expressed by,

$$\log_{10} p = -\frac{2000}{T} + 7.86.$$

The extrapolated B.Pt. is 128.6° C. (*Int. Crit. Tables*, 128° C.)  $\lambda = 9200$  Cals., and  $\lambda/T_b = 22.8$ .

(9) **Methyl Iodide.**—The present measurements give :—

$t^\circ$ C.	0.1	4.3	11.7	34.4
$p$ mm.	142	171	235	569

These data are satisfactorily represented by the equation,

$$\log_{10} p = -\frac{1475}{T} + 7.56,$$

in excellent agreement with the measurements of Brown and Acree,<sup>\*</sup>

<sup>\*</sup> *J.A.C.S.*, 1916, 38, 2145.

and of Robertson and Acree.<sup>4</sup> The extrapolated B.Pt. is 42.8° C. (recorded 43° C.),  $\lambda = 6790$  Cals. and  $\lambda/T_b = 21.5$ .

### Discussion.

It may now be profitable to consider the values of the Trouton constant for the alkyl derivatives of elements of different groups of the Periodic Table. These are set out below.

#### GROUP IN THE PERIODIC SYSTEM.

I.	II.	III.	IV.	V.	VI.	VII.
[Li(C <sub>2</sub> H <sub>5</sub> ) <sub>3</sub> ]		B(CH <sub>3</sub> ) <sub>3</sub> , 21.6			O(CH <sub>3</sub> ) <sub>2</sub> , 22.3	FCH <sub>3</sub> , 21.0
[Na(CH <sub>3</sub> ) <sub>3</sub> ]	Zn(CH <sub>3</sub> ) <sub>2</sub> , 21.4	[Al(C <sub>2</sub> H <sub>5</sub> ) <sub>3</sub> ]		N(CH <sub>3</sub> ) <sub>3</sub> , 21.1	O(C <sub>2</sub> H <sub>5</sub> ) <sub>2</sub> , 20.2	ClCH <sub>3</sub> , 21.2
	Zn(C <sub>2</sub> H <sub>5</sub> ) <sub>2</sub> , 22.2	[Al(C <sub>2</sub> H <sub>5</sub> ) <sub>3</sub> ]	Ge(C <sub>2</sub> H <sub>5</sub> ) <sub>4</sub>	N(C <sub>2</sub> H <sub>5</sub> ) <sub>3</sub> , 21.9		BiC <sub>2</sub> H <sub>5</sub> , 21.4
[Na(C <sub>2</sub> H <sub>5</sub> ) <sub>3</sub> ]	Hg(CU) <sub>2</sub> , 21.0	[Ga(CH <sub>3</sub> ) <sub>3</sub> ]	Sn(CH <sub>3</sub> ) <sub>4</sub>	P(C <sub>2</sub> H <sub>5</sub> ) <sub>3</sub> , 22.8	Si(CH <sub>3</sub> ) <sub>2</sub> , 22.3	ICH <sub>3</sub> , 21.5
	Hg(C <sub>2</sub> H <sub>5</sub> ) <sub>2</sub> , 23.4	[Ga(CH <sub>3</sub> ) <sub>3</sub> ] <sub>2</sub>	21.2		Si(C <sub>2</sub> H <sub>5</sub> ) <sub>2</sub> , 21.7	ClC <sub>2</sub> H <sub>5</sub> , 22.1
		[In(CH <sub>3</sub> ) <sub>3</sub> ] <sub>2</sub>				IC <sub>2</sub> H <sub>5</sub> , 21.7
		[Tl(C <sub>2</sub> H <sub>5</sub> ) <sub>3</sub> ]				

The value given for boron trimethyl is calculated from the vapour pressure data of Stock,<sup>5</sup> and those for the alkyl halides from the vapour pressure data given in *International Critical Tables*. Values for the ethers and thioethers have previously been given.<sup>1</sup> The physical properties of the alkali metal alkyls indicate association in the solid state; and cryoscopic measurements with lithium ethyl are said to indicate six-fold association. According to Louise and Roux,<sup>6</sup> aluminium triethyl and aluminium tripropyl are associated in the vapour state. The Trouton constant for gallium triethyl evaluated from the vapour pressure measurements of Dennis and Patnode<sup>7</sup> is 23.9, suggesting slight association, in the liquid phase. From cryoscopic data these observers suggest association to double molecules. The Trouton constant of gallium trimethyl is 23.9 too,<sup>8</sup> which may similarly imply slight association. Indium trimethyl is a solid, which from cryoscopic data of Dennis<sup>9</sup> appears to be associated four-fold. The extent of association of thallium triethyl has not been estimated, but since this substance is a liquid of very high B.Pt., it may well be abnormal. From the vapour density and from cryoscopic data, Dennis<sup>10</sup> has concluded that germanium tetra ethyl is unassociated.

None of the other substances examined in the present work and listed above show a noticeable divergence from the "normal" value of the constant, about 21.7, and suggesting that none are appreciably associated. The rather high value for mercury diethyl is suggestive of slight association, but in this particular case the errors are most noticeable, and the result may be accidental.

Thus in so far as the table is representative and complete, the only compounds showing association are the alkyl derivatives of the elements of Group I. (alkali metals) and of the heavier elements of Group III.

<sup>4</sup> *Am. Chem. J.*, 1913, 49, 474.

<sup>5</sup> *Ber.*, 1921, 54, 531.

<sup>6</sup> *Comptes Rendus*, 1888, 107, 601; *Bull. Soc. Chim.*, 1888, (2), 50, 511.

<sup>7</sup> *J.A.C.S.*, 1932, 54, 182.

<sup>8</sup> Kraus, *Proc. Nat. Acad. Sci.*, 1933, 19, 292.

<sup>9</sup> *J.A.C.S.*, 1934, 56, 1047.

<sup>10</sup> *Ibid.*, 1925, 47, 370.

An explanation of this peculiarity on the basis of the electronic theory of valency cannot at present be suggested. The physical properties of the beryllium and magnesium alkyls suggest, however, that these compounds may be associated, so that the conclusions may not be as simple as just stated.

### Summary.

The vapour pressures of a series of metallic and non-metallic alkyls have been measured over a range of temperature. The Trouton constants thus calculated indicate that these compounds show little, if any, association. The degree of association of other similar substances is discussed.

## THE CRITICAL SOLUTION TEMPERATURES OF SOME ALIPHATIC ACIDS WITH NITROMETHANE.

BY G. BROUGHTON AND D. C. JONES.

*Received 9th January, 1936.*

Few determinations have been made of the solubility relations of the higher fatty acids, particularly in solvents with which they are only partially miscible. A number of binary systems, containing a low aliphatic acid as one component,\* have, however, been fully investigated, and the usefulness of the critical solution temperature of the system as a criterion of their purity demonstrated. In the present work the solubility curves of a number of the higher acids with nitromethane have been obtained. Nitromethane was chosen as the second component because it gives critical solution temperatures over a convenient temperature range with all the acids from caproic to stearic and is easily obtained pure. The use of a single liquid for second component also permits the relation between solubility and increasing chain length to become apparent.

Since there are few methods of estimating the purity of the higher fatty acids and their freedom from homologues, the effect of adding a third acid upon their critical solution temperature was also investigated.

### Experimental.

**Purification of Materials.**—The acids were the same as those used in a previous paper,<sup>4</sup> in which their preparation and physical constants are given.

Nitromethane was prepared from sodium monochloracetate by treatment with sodium nitrite.<sup>5</sup> After treating with ice-cold 85 per cent. sulphuric acid and washing with saturated sodium sulphate solution, it was

\* E.g., formic acid-benzene,<sup>1</sup> acetic acid-carbon disulphide,<sup>2</sup> acetic acid-cyclohexane,<sup>3</sup> butyric acid-water.<sup>4</sup>

Stearic . . .	114.0 ± 0.1° C.

fractionated. The fraction used had an ethereal odor,  $n_D^{25}$  1.3796;  $d_4^{25}$  1.1308.

**Determination of the Solubility Curves.**—The synthetic method, as described by Jones and Betts,<sup>\*</sup> was used with the substitution of mechanical shaking. Liquids were introduced into the glass tubes by pipettes, solids by a small glass funnel, the tip of which reached to the bottom of the tubes. Care was taken to ensure that all apparatus was dry. The temperatures at which complete miscibility occurred were taken to 0.05° C. by thermometers carefully standardised against a set of standard thermometers having N.P.L. certificates. The miscibility temperatures were very sharp especially for the lower acids and critical phenomena were also marked.

The results are shown in Tables I. and II., and Fig. 1 illustrates a typical solubility curve.

FIG. 1.

### Effect of Homologues Upon the Critical Solution Temperature.

The effect of adding a third acid upon the consolute temperatures of caproic and palmitic acids was also roughly investigated. Mixtures containing 1.5 per cent. of another fatty acid were made up by direct weighing, and a few points in the neighbourhood of the critical solution temperature determined, using the mixture in place of the pure acid. The results are shown in Table III.

TABLE III.

System.	Added Impurity.	Percentage Required to Raise or Lower C.S.T. 0.1° C.
Caproic acid—Nitromethane	Butyric acid	0.16
" " "	iso-Butylacetic acid	0.51
" " "	Caprylic acid	0.29
Palmitic acid—Nitromethane	Stearic acid	1.17
" " "	Oleic acid	1.06

<sup>\*</sup> Jones and Betts, *J.C.S.*, 1928, 1177.

### Discussion.

It will be seen that the solubility curves take the usual form, but with the exception of caproic and pelargonic acids the mean concentration lines curve within about  $1^\circ$  of the critical solution temperature. A possible explanation of this is that the acids used may still have been slightly impure.<sup>6</sup>

The solubility of the acids is seen to decrease in a regular manner with their position in the homologous series. In Fig. 2 the critical solution temperatures are plotted against the number of carbon atoms in the acid giving a perfectly smooth curve, from which the critical solution temperatures of acids not investigated can be predicted with an accuracy of at least  $1^\circ$ . In the same figure are shown data for aniline-hydrocarbon systems<sup>7</sup> which give a similar smooth curve, showing, however, a minimum at hexane. The diminishing rise in critical solution

FIG. 2.

temperature with each addition of a  $-\text{CH}_2$ -group would be expected, since the influence of the carboxyl group, at first predominant, becomes smaller with each addition, the molecule finally behaving almost as a hydrocarbon. The effect of the aliphatic hydrocarbons on the critical solution temperature with nitromethane has been determined already by H. J. Moss in this laboratory. A linear relationship was found, the slope being almost the same as that obtained in this work with the higher aliphatic acids. These two sets of results afford a good opportunity of testing the Langmuir theory of independent surface action,<sup>8</sup> and this will be done in a further communication.

It is apparent from Table III. that the critical solution temperatures of the aliphatic acids cannot be used as sensitive criteria of their purity.

<sup>7</sup> Shepard, Henne, and Midgley, *J. Am. Chem. Soc.*, 1931, **53**, 1948.

<sup>8</sup> *Colloid Symposium Monograph*, **3**, 1925, 48.

Even in the case of caproic acid the effect produced by impurity is small, and in most cases the setting point is a more sensitive test.

### Summary.

The critical solution temperatures of caproic, caprylic, pelargonic, lauric, palmitic and stearic acids with nitromethane have been determined and found to increase regularly with increasing molecular weight of the acid. The effect of homologues upon the critical solution temperatures has also been investigated.

During the period when this work was done one of the authors (G. B.) held a studentship of the University of London, and also obtained a research grant from the Chemical Society which defrayed, in part, the cost of the materials.

## THE INFLUENCE OF PHYSICAL STATE ON THE ABSORPTION AND FLUORESCENCE SPECTRA OF ORGANIC SUBSTANCES.

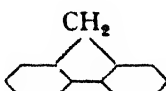

BY P. K. SESHAN, *Research Scholar, Indian Association for the Cultivation of Science, Calcutta.*

*Received 7th January, 1936.*

### 1. Introduction.

In the course of our investigations on the absorption and fluorescence spectra of aromatic compounds, we had occasion to study some of them in different physical states: vapour, liquid, solid, solutions in different solvents, and also solid solutions. The results are reported in the present paper. The spectra in the different states are compared with those in the vapour state, and the influence of the proximity of the surrounding molecules (*a*) of the same kind as the absorbing or the fluorescing molecule, as in liquid or solid, (*b*) of different kind, as in solutions, on the absorption and fluorescence spectra, is discussed.

### 2. Absorption Spectra.

The three aromatic hydrocarbons, fluorene  naphthalene , and perylene  were chosen for these investigations, since their absorption bands are sharp and well-defined, and attention was confined to the first few bands, which are very prominent.

The experimental arrangements adopted in these measurements were the same as those described in an earlier publication <sup>1</sup> by the author, to

<sup>1</sup> *Proc. Ind. Acad. Sci.*, 1936, 3.

which the reader may be referred for the details. We shall content ourselves with giving the final results.

In Table I. are given the absorption data for fluorene under different physical conditions.<sup>2</sup> The positions of the absorption maxima are given in wave-numbers, and in the next column of the table are given the differences in wave-numbers between successive absorption bands.

Table II. gives similarly the absorption data for naphthacene and perylene. These two substances were studied in great detail in solutions. Two sets of investigations were made. In the first set the solvent was kept the same, and the absorption spectrum of the solute was studied for different concentrations. Owing to the low solubility of both these

<sup>2</sup> As we mentioned in an earlier paragraph, we are giving here the positions of only the first few prominent bands in the absorption. For the complete absorption spectrum of this substance, as also of naphthacene and perylene, see *Proc. Ind. Acad. Sci.*<sup>1</sup>

substances, all the concentrations studied were small. *For these dilute solutions, the positions of the absorption bands were found to be practically independent of the concentration.*

In the second set, the absorption spectrum of the substance was studied in different solvents, and the positions of the bands were found to vary, as will be seen from the table, from solvent to solvent. This variation will be clear from Figs. 1 and 2, in which are exhibited the absorption spectra of naphthacene and perylene respectively, in three typical solvents (alcohol, benzene, and carbon bisulphide), taken in juxtaposition with the help of a Hartmann diaphragm placed in front of the spectrograph (Hilger Quartz  $E_2$ ).

### 3. Discussion of Results.

On comparing the absorption spectra of a substance in the different physical states, we observe, as we pass from vapour to the solutions and thence to the liquid and solid states, (1) a progressive broadening of the absorption bands, and (2) a progressive shift of the band system as a whole towards the red, the relative dispositions of the components of the band system remaining practically unaltered.

Since the *relative* positions of the component bands are determined by the vibrational frequencies of the molecule, in the normal and in the excited states, while the position of the band system as a whole depends on its electronic frequency, result (2) indicates that the vibrational frequencies of a molecule remain practically the same in the different physical states, whereas its electronic frequency diminishes progressively as we pass from the vapour to more and more dense states.

The actual magnitude of the shift of the bands towards the red as we pass from the vapour to the different physical states is given in the following table :—

TABLE III.—DISPLACEMENTS OF THE BANDS WITH REFERENCE TO THEIR POSITIONS IN THE VAPOUR STATE.

Substance.	Solution in $C_2H_5OH.$ $CS_2.$		Liquid.	Solid.
Anthracene . . . .	880		—	2000
Naphthacene . . . .	850	1520	—	1580
Perylene . . . . .	1050	1920	—	—
Phenanthrene . . . .	880		—	1440
Fluorene . . . . .	430		880	1200

A comparative study of the positions of the bands for the solutions in the different solvents throws some light on the factors that influence the shift of the bands. In Table II. the solvents are arranged in the order of the increasing shift of the absorption bands, and on careful examination we find that this is also the order of increasing refractive index of the solvent, and of the solutions also, since the concentrations are small; *i.e., the greater the refractive index of the medium in which the absorbing molecules are dispersed, the greater is the shift, towards the red, of the absorption bands of the molecules, from their positions in the vapour state.*

An examination of the shifts in other physical states shows that the above result is very general, and holds not only for the solutions in

different solvents, but also for other physical states in which the absorbing molecules may be present, *i.e.* the result holds whether the molecules in the medium surrounding the absorbing molecules are of the same kind as the absorbing molecules or are of a different kind. For example, the molten liquid has a higher refractive index than the solutions, and the solid higher than the liquid. The shifts of the absorption bands from their positions for the vapour state follow also the same order, *vis.*, solutions, liquid, solid.

If this conclusion is correct, since the refractive index of a solution changes with its concentration, we should expect the absorption bands to shift as the concentration increases. For the low concentrations studied by us, the change in the refractive index should be too small to give an appreciable shift of the bands; the apparent independence of the positions of the bands in these dilute solutions, on the concentration, should doubtless be attributed to this circumstance. With suitable solutions, however, whose refractive indices can be varied considerably by changing the concentration, *e.g.*, phenanthrene in ether, the absorption bands of the concentrated solution are found experimentally to be slightly displaced towards the red, with reference to the corresponding bands of the dilute solution.

It should be remarked here that, in the solutions that we are considering, the solute molecules, *viz.*, naphthacene, perylene, phenanthrene and fluorene, are presumably all non-polar, *i.e.*, have no permanent electric dipole moment. When, on the other hand, the solute molecules are polar, it is quite possible that the polarity of the solvent molecules may also have an influence on the absorption spectra, and the refractive index of the medium may not be the main factor influencing the absorption, as is the case with non-polar solutes.

#### 4. Influence of the Refractivity of the Medium on the Positions of the Absorption Bands.

The influence of the refractivity of the medium in shifting the absorption bands may be explained in the following manner. In the usual Lorentz treatment of the refractivities of dense media, it is shown that the actual electric field (of the light-vector) acting on any given molecule in the medium, is greater than the "field in the medium" by a factor  $\theta$  given by the relation

$$\theta = 1 + 4\pi\chi/3 = (n^2 + 2)/3,$$

where  $\chi$  is the polarisation of the medium per unit volume per unit field, and  $n$  is its refractive index. The consequence is an apparent increase in the refractivity of the densely packed molecules as compared with that of the molecules in the gaseous state.

This increase of refractivity due to close-packing may also be viewed from a slightly different angle, which is helpful to our present problem. It may be shown analytically that the influence of the Lorentz polarisation field may alternatively be considered as causing a diminution in the electronic frequencies of the molecules, and consequently an increase of refractivity as required. Assuming that the molecules has only one absorption frequency  $\nu_0$ , and that the refractive measurements refer to a frequency  $\nu$ , the change in  $\nu_0$  due to the Lorentz field will be given by

$$\frac{2\nu_0 \delta\nu_0}{\nu_0^2 - \nu^2} = \theta - 1.$$

For alcohol,  $n = 1.36$  and  $\theta = 1.28$ ;  $\delta\nu_0/\nu_0$  should be considerably less than  $(\theta - 1)/2$ , and may have about a third or fourth of this value; *i.e.*,  $\delta\nu_0/\nu_0 \sim 0.03$ . Since the observed shifts of the absorption bands from the vapour to the solution are of this order of magnitude, we may presume that the influence of the physical state is mainly through the refractivity of the medium and the corresponding Lorentz polarisation field acting on the absorbing molecule.

It should be remarked, however, that the intermolecular electric fields, which would be quite large especially in the solid state, may conduce to a Stark splitting of the energy levels of the molecules, and may also be a contributory cause for the observed shifts.

### 5. Fluorescence Spectra.

The influence of the physical state on *fluorescence* is very similar to that on absorption. Taking for examples fluorene and phenanthrene, the positions of their fluorescent bands for the alcoholic solution and for the solid are entered in Table IV.

TABLE IV.—FLUORESCENCE SPECTRA.

Fluorene.				Phenanthrene.			
Alcoholic Soln.		Solid.		Alcoholic Soln.		Solid.	
$\nu$ .	$\Delta\nu$ .	$\nu$	$\Delta\nu$	$\nu$ .	$\Delta\nu$ .	$\nu$ .	$\Delta\nu$ .
22260		21570		22260		21730	
	1490		1490		1260		1250
23750		23060		23520		22980	
	1400		1380		1280		1220
25150		24440		24800		24200	
	1230		1230		1230		1300
26380		25670		26030		25500	
	1240		1280				
27620		26950					

Here again, just as in absorption, there is a bodily shift of the bands as we pass from the alcoholic solution to the solid state; and the magnitude of the shift is also of the same order as in absorption.

The intervals between the successive fluorescence bands are independent of the physical state, even as the intervals between the absorption bands are. Moreover, the intervals between the fluorescence bands have the same magnitude as the intervals between the corresponding absorption bands.

The positions of the fluorescence bands for solutions of

perylene in alcohol, benzene and carbon bisulphide, are given in Table V.

The relative positions of the fluorescence bands in the three solutions are clearly brought out in Fig. 3, in which the three fluorescence spectra are exhibited side by side. As will be seen from Table V. the fluorescence

TABLE V.—FLUORESCENCE OF SOLUTIONS OF PERYLENE.

Solvent.	First Band.	Second Band.
Alcohol . . .	21270	22720
Benzene . . .	21000	22460
Carbon bisulphide	20380	21810

bands shift towards the red by  $270\text{ cm.}^{-1}$  as we pass from the alcoholic solution to that in benzene, and again by  $890\text{ cm.}^{-1}$  as we pass from the solution in benzene to that in carbon disulphide. The corresponding shifts in the absorption bands of the solutions are 210 and  $870\text{ cm.}^{-1}$  respectively.

In conclusion, the author desires to express his grateful thanks to Professor K. S. Krishnan, for his keen interest and constant encouragement in the course of this work.

## ABSORPTION OF AIR BY MINERAL OILS.

BY A. GEMANT.

*Communicated from the Engineering Laboratory, Oxford University.*

*Received 13th February, 1936.*

### 1. Introduction.

The purpose of this investigation was to measure the absorption of air by mineral oils in the most important working range of temperature, that is, from  $20^{\circ}$  to  $80^{\circ}\text{ C.}$  Whereas a fairly considerable amount of literature exists on absorption of gases by inorganic as well as organic liquids, some even of recent date,<sup>1</sup> extremely little is known about corresponding data on mineral oils. The reason probably is that since oils do not possess a well-defined composition, reproducible and characteristic data are not to be expected as for liquids with known composition. On the other hand, mineral oils are so important for their application to electrotechnics, that it seemed justifiable to look further into the question. The author is much indebted to Mr. B. L. Goodlet for having raised this suggestion.

Oil is often used in combination with paper or pressboard for impregnated insulating materials. Since air is deleterious to the insulating property of the compound, the oil is degassed before impregnation begins. Degassing usually takes place at about  $100^{\circ}\text{ C.}$ ; it is therefore important to know the changes with temperature of the absorption coefficient in the above range.

In the International Critical Tables<sup>2</sup> a few data for oxygen, nitrogen and hydrogen are published, referring to a transformer oil of Pennsylvanian origin. Whereas there is a fairly large increase of the absorption coefficient from  $25^{\circ}$  to  $80^{\circ}\text{ C.}$  with respect to hydrogen, there is only a slight increase with respect to nitrogen and a slight decrease with regard to oxygen. One would expect a slight increase for air containing roughly 80 per cent. of nitrogen.

In a recent investigation, F. M. Clark<sup>3</sup> gives values for the absorption coefficient in oils, which show a definite increase of some 10 per cent. in the temperature range in question.

In the following pages, first the method will be described, followed by a few test measurements on water, in order to check the method. We shall then give the results for several oils and deduce therefrom a general

<sup>1</sup> S. Hamai, *Chem. Soc. Japan Bull.*, 1935, 10, 5.

<sup>2</sup> *Intern. Crit. Tables*, Vol. III., McGraw-Hill, 1928.

<sup>3</sup> F. M. Clark, *Frankl. Inst. J.*, 1933, 215, 39.

will give the absorption coefficient at a partial pressure of the air  $P - p'$ . Its value at the normal pressure  $P_0$  is therefore

$$\alpha = \frac{T_0}{T} \frac{P - p}{P - p'} \frac{V}{vM} \quad (2)$$

instead of (1).

First a few absolute measurements were taken, which are tabulated in Table I. In the first column is given the atmospheric pressure  $P$  in mm. mercury (where necessary), in the second the room temperature  $t$  in degrees Centigrade. The third column contains the bath temperature  $t'$  in degrees Centigrade, the fourth the mass  $M$  of the water, and the fifth the volume absorbed,  $V$ . The absorption coefficient  $\alpha$  calculated by means of (2) follows, compared with its value known from the literature. To compute the latter, the International Critical Tables have been used, which contain the values for  $K$ , Henry's law constant, as measured by Winkler.  $\alpha$  was calculated from  $K$  by means of the formula

$$\alpha = \frac{0.95 \times 10^6}{K}.$$

TABLE I.—ABSOLUTE TEST MEASUREMENTS WITH WATER.

$P$ in mm. Mercury.	$t$ in °C.	$t'$ in °C.	$M$ in gr.	$V$ in c. c.	$\alpha$ Calculated.	$\alpha$ (Winkler).
—	22.4	22.4	115.35	2.13	0.0170	0.0180
—	22.4	22.4	163.80	3.03	0.0170	0.0180
758	26	42.5	151.7	2.13	0.0134	0.0139

As can be seen, the measured and known values of  $\alpha$  agree within 5 per cent., which is satisfactory for our purpose.

Two test measurements for the difference method follow, which is even more important from the standpoint of the oil measurements. Table II. contains the atmospheric pressure, the room temperature, the two respective bath temperatures, the mass of the water and the measured volume difference  $v$ . In the last column there is the value of  $v$  as calculated from the known values of  $\alpha$  and using the following equation, deduced from (2) :

$$v = \frac{T}{T_0} \frac{M}{P - p} [(P - p_1') v_1 \alpha_1 - (P - p_2') v_2 \alpha_2] \quad (3)$$

In this equation the indices 1 and 2 refer to the two bath temperatures.

TABLE II.—DIFFERENCE TEST MEASUREMENTS WITH WATER.

$P$ in mm. Mercury.	$t$ in °C.	$t_1'$ in °C.	$t_2'$ in °C.	$M$ in gr.	$v$ Measured.	$v$ (Computed from Values for $\alpha$ of Winkler).
761	25	23	43	143.22	0.72	0.73
745	18	20	40	129.3	0.73	0.69

The agreement is again satisfactory.

#### 4. Results on a Special Oil Sample.

Before giving the summarised results on different oil samples, we indicate the detailed results on a special oil (No. 2 of the list in Table III.). First the specific volume had to be measured as a function of temperature.

Fig. 1 shows the result as a straight line between  $10^\circ$  and  $100^\circ$ . The absolute measurement is indicated in Fig. 2. The abscissæ are minutes from the beginning of shaking and the ordinates c.c. of air passing into the oil. In eight minutes the final value

$$V_{18} = 12.62$$

was reached. Using equation (1), we have for  $18^\circ$  C.

$$\alpha_{18} = 0.088.$$

As to the difference measurements between  $18^\circ$  C. and  $80^\circ$  C., two measurements were taken, one with two hours waiting for equilibrium, yielding 0.51 c.c.; another with three hours waiting, yielding 0.45 c.c. These data have to be corrected for the waiting time.

Fig. 3 shows the absorption rate with the oil in rest, the abscissæ being again minutes, the ordinates c.c. In one hour the absorbed amount is 11.5 per cent. of the total; in two hours, 20.6 per cent., which corresponds

to a value of 28.6 per cent. for three hours (assuming the function to be exponential). The corrected values are respectively 0.64 c.c. and 0.63 c.c., showing a good agreement. This means that  $V_{80} = 13.25$  c.c.

From equation (1) it is easy to deduce

$$\alpha_2 = \frac{V_2 v_1}{V_1 v_2} \alpha_1 \quad (4)$$

The factor of  $\alpha_1$  in this equation should be called  $(1 + k)$ , if  $\alpha_1$  refers to room temperature and  $\alpha_2$  to  $80^\circ$  C. The value of  $k$  will indicate directly the temperature variation of the absorption-coefficient. Apply-

FIG. 1.—Specific volume ( $v$ ) as function of temperature. (Oil Nr. 2.)

FIG. 2.—Absorbed volumes of air as function of time. Oil shaken. (Oil Nr. 2.)

ing (4) to our case above, we get

$$k = -0.002,$$

indicating a difference in  $\alpha$  between 18 and  $80^\circ$  C. of 0.2 per cent.

Assuming  $v$  to be correct to 10 per cent., which is justifiable according to the test with water, we may conclude that the difference between  $\alpha_{10}$  and  $\alpha_{20}$  is certainly not greater than roughly  $\frac{1}{2}$  per cent.

FIG. 3.—Absorbed volumes of air as function of time.  
Oil in rest.  
(Oil Nr 2.)

### 5. Results on Several Oils.

In Table III. the eight samples of oil which have been investigated are characterised either by some data concerning their origin and grade or else, if such were not available, by their viscosity at 20° and 60° C.

TABLE III.—DATA OF OILS INVESTIGATED.

No.	Supplied by	Origin of Oil.	Grade to British Standard Specification	Viscosity Data in Poise.
1	Silvertown Lubricants	Russia	A. 30	---
2	"	America : Kansas, Oklohama	A. 0	---
3	"	Russia	B. 30	---
4	"	America : Pennsylvania	B. 0	---
5	"	---	A. 30	23°, 0.21 ; 58°, 0.076
6	Shell-Mex and B.P.	---	---	21°, 0.060 ; 60°, 0.022
7	"	---	---	21°, 2.0 ; 60°, 0.21
8	Vacuum Oil Co.	---	---	" Mobiloil BB "

Whereas the first six varieties were more or less light oils, the last two were chosen as of the more viscous type. Table IV. includes the results obtained from these eight samples by means of the procedure outlined above. The first column contains the number of the oil in accord with Table III. ; the second the lower bath temperature, which varied according to the room temperature (the higher temperature was always 80° C.) ; the third  $M$ , the mass of the oil ; the fourth and fifth the two respective specific volumes  $v_1$  and  $v_2$ . The total air volume  $V$ , and the difference volume  $v$  come next, followed by  $\alpha$  at room temperature and  $h$  according to equation (4).

Apart from samples 6 and 7, none of the values of  $h$  exceed a few tenths per cent. But since  $h$  for oil 6 is  $-2$  per cent. (temperature coefficient negative), and for oil 7  $+2$  per cent. (temperature coefficient positive), these somewhat higher values do not seem to be of great importance. Considering the bulk of the results, and allowing for 0.5 per cent. error in

8	20	111.6	1.139	1.189	10.60	0.46	0.078	— 0.003

$k$ , we may express the result by saying that the temperature variation of the absorption coefficient is practically zero between  $20^\circ$  and  $80^\circ \text{C.}$ ; at all events, generally not greater than roughly 1 per cent.

Taking the difference in absorbed air volume per mass unit of oil, the temperature coefficient is of the order of  $\div 5$  per cent. But this coefficient is practically identical with the corresponding volume expansion. Although a given mass of oil absorbs 5 per cent. more air at  $80^\circ$  than at  $20^\circ \text{C.}$ , the absorbed amount per volume unit of oil is practically the same at both temperatures.

As to the absolute amount  $\alpha_1$ , the results are in agreement with earlier observations, as well as to its general order of 10 per cent. and to its decreasing with increasing viscosity of the oil. (Oils 7 and 8 have the highest viscosity, oil 6 the lowest, in the series.)

## 6. Thermodynamic Conclusions.

Applying the second law of thermodynamics to the absorption process, the equation

$$\frac{d \ln \lambda}{dT} = - \frac{Q}{RT^2} \quad . \quad . \quad . \quad (5)$$

is obtained. Here  $\lambda$  is the Ostwald absorption coefficient, which is related with  $\alpha$  by

$$\alpha = \frac{T_0}{T} \lambda.$$

$Q$  is the molar latent heat of absorption. Equation (5) allows us to compute the temperature coefficient of  $\alpha$  in terms of the latent heat.

Suppose that the absorption is a purely physical process, and that no interchange whatever occurs between the molecules of the solvent and that of the gas. This means that the increase in total energy  $U$  during absorption of one mol of a gas is zero; since

$$U = A - Q,$$

where  $A$  = the maximal work,

$$Q = A \quad . \quad . \quad . \quad (6)$$

But  $A$  is known, if  $\lambda$  is known, since

$$A = RT \ln \lambda \quad . \quad . \quad . \quad (7)$$

Combining (5) and (7), we have

$$\frac{d \ln \lambda}{dT} = - \frac{\ln \lambda}{T} \quad . \quad . \quad . \quad (8)$$

Thus, for  $\lambda > 1$ , the temperature coefficient of  $\lambda$  ought to be negative, with  $\lambda < 1$  negative. However, it is easy to show that equation (8) is not fulfilled at all in the case of oil and air.  $\lambda$  is of the order of 0.1, which

means that  $\frac{d \log_{10} \alpha}{dt}$  ought to be of the order of 0.003, whereas our experiments indicate that it is less than 0.00007.

In comparison, it may be shown that (8) is approximately fulfilled in the case of hydrogen and oil (taken from the data in the International Critical Tables). The mean value for  $\alpha$  appears to be 0.06, yielding for the right side of (8) 0.0036. Since  $\alpha$  increases from 0.051 at 25° to 0.069 at 80°, the left side of (8) appears to be 0.0024,—the same order as the right.

In other words, hydrogen fulfils (8) and therefore (6), indicating a purely physical absorption. Air, and especially oxygen (see the Introduction), on the other hand, do not fulfil (6), indicating a certain interchange between the oil and gas molecules.

Assuming, therefore,<sup>4</sup> that this interchange is involved with a certain drop  $q$  in the total energy, we obtain in place of (6)

$$Q = A + q \quad (9)$$

Whereas it does not seem clear what kind of interchange may occur with nitrogen, there is no difficulty in explaining the effect with oxygen as a kind of reversible oxidation, forming for instance some labile peroxides with traces of acids always present in oils. Since the experiments indicate  $Q$  to be very small, it follows from (9) that  $q$  must be of the order of  $A$ , which is given by (7).

The conclusion reached is, therefore, that oxygen undergoes a secondary reversible chemical reaction immediately after absorption, and that the latent heat of this reaction is of the order of  $RT \ln \lambda$ . This conclusion is supported by an investigation by the author on the oxidation of mineral oils, which is now in progress.

## 7. Electrotechnical Conclusions.

There is first a remark to be made concerning the degassing of an oil preceding the impregnation process. Since the absorption coefficient is independent of temperature, the heating of the oil during degassing has itself no expelling effect whatsoever, as is sometimes thought. It is only useful in that it helps in removing the water and accelerates the new equilibrium under vacuum.

A second point which has to be discussed, concerns the temperature variation of the breakdown strength of oil. It is known that the latter usually increases with temperature in the range concerned. Clark observed—as already mentioned—a finite increase of  $\alpha$  in the same range and developed a theory<sup>5</sup> which explains the former effect directly by the latter, by assuming that the breakdown strength varies proportionally to the square root of the air content of the oil. In spite of the apparent aptitude of this assumption to explain several observations concerning the variation of the breakdown strength, there are several objections which have to be raised:—

(1) Mainly it should be emphasised that our experimental results indicate an absorption coefficient independent of temperature, although the oils under investigation show the breakdown effect just as well as other oils, as break-down tests with oils Nos. 1–4, between 20 and 80° C. revealed.

<sup>4</sup> G. Tammann, *Z. anorg. Chem.*, 1926, 158, 17.

<sup>5</sup> F. M. Clark, *Electrical Engineering*, 1935, 54, 50.

(2) Our results show how very slowly the equilibrium is reached when the oil is in rest. Now the temperature change in the breakdown effect is immediately observable, after the temperature of the oil has been raised or lowered, although no appreciable change in the absorption equilibrium could have taken place during this short time.

(3) Several authors stressed the point that completely dry oil does *not* show the temperature-breakdown effect at all. This was proved recently by A. Lazarev,<sup>6</sup> who found that the breakdown strength of thoroughly dry oil decreases slightly but continuously with an increase of temperature. The peculiar curve obtained with wet oils can be explained by assuming an equilibrium between water in colloidal and in molecular solution, the second state being preferred at higher temperatures. That colloidal water is more deleterious than dissolved water is well known.<sup>7</sup>

### Summary.

(1) An apparatus and a method are described, based on the manometric principle, to measure the absorption of gases by liquids and its temperature coefficient. They are utilised here in measuring the absorption of air in mineral oils for 20° and 80° C.

(2) It appears from results obtained from different oils that the Bunsen absorption coefficient, referring to the volume unit of oil, is practically constant in the above range of temperature, the variation generally not being larger than 1 per cent.

(3) Thermodynamical conclusions from the above result indicate that the absorption of air in oil is followed by a first step of reversible oxidation process.

(4) Some conclusions are drawn as to the temperature variation of the electrical breakdown strength of oil.

The author is much indebted to Professor R. V. Southwell, F.R.S., for facilities in the Engineering Laboratory, Oxford, and to Messrs. Metropolitan-Vickers Electrical Co., Ltd., for a grant enabling him to carry out this work. Further thanks are due to Messrs. Silvertown Lubricants Ltd., and to Messrs. Shell-Mex and B.P. Ltd., for generous samples of oil put at the author's disposal.

## MAGNETIC SUSCEPTIBILITY AND OTHER PROPERTIES OF BINARY MIXTURES OF ORGANIC LIQUIDS.

BY V. C. G. TREW AND J. F. SPENCER.

*Received 19th February, 1936.*

In a previous investigation,<sup>1</sup> it was shown that the physical properties of mixtures of liquids of a chemically dissimilar type, between which there is the possibility of combination, exhibit more marked deviations from

<sup>1</sup> "Some Physical Properties of Mixtures of Certain Organic Liquids," Trew and Watkins, *Trans. Faraday Soc.*, 1933.

the mixture law than mixtures of chemically similar liquids such as the members of an homologous series, but that even in the latter case considerable deviations do occur. In the present communication, some further binary mixtures are considered, in order to determine whether any general rule can be deduced connecting such deviations with differences in chemical constitution of the liquids mixed. It was thought that differences in molecular weight, and hence size of molecule, of the constituents might be a factor causing deviations from the mixture law. In addition, the presence of positive and negative groups might also contribute to such deviations.

Two groups of mixtures were investigated, the first consisting of mixtures of the aromatic hydrocarbons, benzene and toluene with *meta*-cresol and, for purposes of comparison, a set of mixtures of benzene and toluene. In the second group, mixtures of aniline with *meta*-cresol, nitrobenzene with *meta*-cresol and aniline with nitro benzene were investigated. Measurements of density, specific heat, heat of mixing, refractive index and magnetic mass susceptibility were made.

### Experimental.

A.R. materials were employed throughout, and these were then carefully dried and fractionated until a constant boiling fraction was obtained.

TABLE I.—BOILING-POINTS AND DENSITIES OF PURE LIQUIDS.

Liquid.	Pressure.	Boiling-Pt.	Density $D_4^{20}$ .
Benzene . .	758 mm.	80.5° C.	0.8708
Toluene . .	753 ..	111.0° C.	0.8565
Aniline . .	760 ..	184.0° C.	1.0148
Nitrobenzene .	762 ..	210.6° C.	1.1937
<i>Meta</i> -cresol .	760 ..	202.4° C.	1.0292

The density of the pure liquids was determined, using a standard pyknometer, and was used as a criterion of purity, the values being compared with those given in the *International Critical Tables*. Table I. shows the physical constants obtained for each of

the constituent liquids.

A series of mixtures was then made up, as previously described,<sup>1,2</sup> containing varying weights of the two components, the proportion of each being expressed as moles per cent. of the total composition. The methods employed for the determination of the density, refractive index, and thermal properties were as described previously. The molecular refractivity was calculated from the refractive index, using the Lorentz and Lorenz formula

$$R = \frac{\mu^2 - 1}{\mu^2 + 2} \cdot \frac{m}{d} \text{ where } m \text{ is the molecular weight of the constituent liquid}$$

when pure, or in the case of a mixture, the mean molecular weight. The molar magnetic mass susceptibility was calculated from the magnetic mass susceptibility measured by the method previously described.<sup>1</sup> The results are summarised in the following tables. Tables II. to IV. give the values obtained for the various properties, while in Table V. the maximum percentage deviation has been recorded for each property investigated, with the exception of the specific heat which was not measured to a sufficient degree of accuracy to give comparative values.
